Usually, a negative view prevails in society about both the place and its people because of the illegal development of squatter settlements: Squatter dwellers are regarded as invaders of land and offenders against private property. They may also be seen as overtaxing public services and causing harm to the city—both to its image as a modern place and to its environment if the houses are built in reservoirs and forests. Furthermore, with their traditional values and way of life, they may be blamed for ruralizing the city. On the other hand, seeing squatter housing as a response of the urban poor to their housing problem may bring some sympathy. The term *squatter housing* implies temporariness, although in fact it has been a continuing presence since its first appearance in the late 1940s and early 1950s.

In most countries, early squatter settlements emerged after World War II in the restructuring of the world economy, although Latin America started capitalist production earlier. In the process of the integration of Third World countries into the capitalist world system, modernization in agriculture disturbed the traditional balance in

SQUATTER SETTLEMENTS

Squatter settlements are basically a Third World phenomenon; they are part of the urban landscape of many Latin American, Asian, Middle Eastern, and African countries. Billions of people live in them. For example, in 2003, 55.5% of the urban population in India, 44.1% in the Philippines, 42.6% in Turkey, 37% in South Korea, 36.6% in Brazil, and 33.1% in Argentina lived in squatter settlements.

Turkish cities such as Istanbul and Ankara are frequently sites of low-income communities called *gecekondu*.

Source: Author.

rural areas, and many peasants, in their search for livelihood, left their villages for the cities. In the face of inadequate housing in the cities, they started building their own houses on land that did not belong to them. The first houses were shanty-like structures; they were built in undesirable locations, such as steep hillsides and riverbanks, close to industrial areas, mostly in old city centers, so that their dwellers could find work and save transportation costs. As these locations disappeared under the migration waves from rural areas, squatter settlements started developing on the peripheries of cities. They were built in faraway areas where no infrastructure and services were available. They were expected to disappear as rural migrants became established in the city and found permanent jobs that would enable them to pay for their housing. However, this expectation proved to be wrong. The level of industrialization in Third World countries lagged behind their level of urbanization, and as a result,

there were not enough jobs in the formal sector to absorb newcomers to the city. Furthermore, the cities lacked affordable housing; Third World states had industrialization as their priority, ignoring other sectors, including housing. Thus, the people themselves had to transform the unoccupied peripheral land into livable environments. They used their meager resources, along with their social networks (mostly kin and fellow villagers) to construct houses and to satisfy basic needs so as to survive in the middle of nowhere. In contrast to the view that squatter settlements destroy nature, they planted trees, as in the case of Turkey, in their endeavor to create environments like the ones back in the villages. Over the years, some squatter settlements developed into established neighborhoods, and their initially shanty-like structures changed into sturdy buildings, while others retained their initial features.

The differences between squatter settlements in different countries should be noted. Several

factors account for the differences. The level of economic development of the country, its political system, its historical background, and the availability of public land are some. As an example, treasury land is abundant in Turkey: The Turkish republic inherited from the Ottoman Empire vast tracts of land that existed outside private ownership. This made it easier for governments, in their pursuit of votes, to legalize squatter settlements. The legalization of squatter settlements has been both a drawback and an advantage. On the one hand, it has aggravated the “squatter problem,” as more and more people began to build squatter houses in the hope of future ownership of their homes; on the other hand, it has contributed to the improvement of squatter settlements, where people, in their expectation that they would own the houses one day, felt free to invest in them, spending money to upgrade them. In Nairobi, Kenya, unlike in Turkey, only temporary structures are permitted on public land; they are rented out, and no improvements are allowed in them. The outcome is decaying houses—mud huts—without basic infrastructure. This situation causes squatter dwellers much inconvenience and resentment and creates health problems. Due to these outcomes, the World Bank maintains that granting residents legal title to their land is key to improving housing standards.

The political system of the country is another factor that affects squatter housing. In those countries where elections are held periodically, political parties are inclined toward populism, promising legalization of squatter settlements during election times. On the other hand, in military regimes, squatter settlements are either strictly prohibited, as they were in Pinochet's Chile, or are rendered invisible, when the state pays no attention to them and to their poor and powerless residents, as in Bolivia when it was under military rule.

Furthermore, if traditional values regarding land tenure prevail, the illegal occupation of land is more easily tolerated. *Usufruct rights*, that is, the right of enjoying the use of property on the condition that one does not cause any harm, can empower squatter builders against the state to claim that they own their houses since they have been living in them for many years. Conflict arises when modern values, such as private property

ownership, compete with traditional ones or render them out of date.

In the initial development of squatter settlements, land invasion is the major issue. In some cases, this process may take the form of an organized mass invasion, as in the case of Lima (Peru) forming housing associations or cooperatives, getting technical advice and support from professionals (architects, engineers, lawyers), occupying the land collectively, and setting up community kitchens while the squatter settlement is under construction. In some other cases, ad hoc invasion prevails, with people hearing from each other about the availability of land, asking their relatives and coworkers to join them, and helping one another in the construction of houses. Solidarity is of central importance in this process. After the invasion of land and the construction of houses, the second issue is to bring infrastructure and services to the settlement; and this is also done collectively. But as the settlement becomes established and the residents settled over the years, the initial tendency of mutual help and cooperation may disappear, and competition and conflict may take their place, especially when families start enjoying some social mobility in their lives in the city. Additionally, although squatter settlements are originally built for providing shelter for the urban poor, this status changes over the years in many instances; commodification of squatter housing becomes the order of the day, and rent concerns largely shape people's relationship with their squatter houses. Squatter settlements turn into dense environments dominated by concrete buildings. Also, as in São Paulo, the formal sector, such as chain stores and banks, may start creeping into squatter settlements to benefit from the consumption desire of their dwellers, which is fueled by the media. Another turn in the development of squatter settlements concerns violence and crime. As in the case of Brazil, portions of many squatter settlements may come under the control of street gangs, and with their own rules and power structure, they may develop into a “parallel society.”

In brief, squatter housing shows a great variety: It differs in different countries and cities, as well as between the past and present. The future of squatter housing is another question to

consider. Squatter settlements are more of a product of modernity, in which nation states and import-substituting industrialization regulated by the state are the main actors in Third World countries. Since the 1990s, this situation has changed following the disintegration of the Soviet Union. The catchword *globalization* is the order of the day, and urban space is gaining much significance under the dynamics of neoliberalism. The private sector, with its transnational partners, is after the profit to be made in city spaces. Regeneration, redevelopment, transformation, and rehabilitation, along with clearance, are spoken of more than ever in the context of squatter settlements. Developers, including large multinational construction companies and municipal governments, want the land occupied by squatter houses, to “develop” it. Populist politics toward squatter dwellers disappears in this case. As squatter settlements are demolished to open up space to the private construction sector for projects that address the affluent classes, such as gated communities and shopping malls, squatter dwellers are displaced. Depending on the democratization of society and the prevalent views about squatter housing and their dwellers, displaced families may be given some rights, such as ownership in an apartment complex built by the municipality, or they may lose their homes and end up in the street. The latter case poses a serious problem for the future of globalizing societies in their relationship with the urban poor. As squatter housing, a compensation for the limited welfare system of Third World societies, disappears, the urban poor face a bleak future and may fall into despair, which may breed violence and illegality. The problem in this case is not squatter housing but the lack of low-cost housing. On the other hand, in those societies and cities that are relatively untouched by the effects of globalization, squatter settlements turn into derelict areas that are outside the attention of the state, while their population is marginalized and excluded more than ever, and in the public view, they are more closely associated with crime and violence: As better-off classes retreat into their own housing and consumption environments, their fear of squatter settlements increases. This fear may be based more on the “talk of crime,” as in the case of Brazil, than on real instances of

crime. This points to the increased tension between squatter dwellers and better-off classes in the city. International agencies, such as the World Bank, attempt to intervene to help the urban poor, for example, by providing credits to squatter dwellers, but this effort remains too limited to change the overall outcome. In brief, the future of squatter settlements and their poor residents looks bleak.

STATE

A state is a politically organized territory with a sovereign government. The concept of the *state* is similar to that of *country*, which is the term used in popular discourse. However, the term *country* has other meanings (e.g., a rural landscape) and is avoided in academic writing and other circumstances where precision in meaning is necessary. At the same time, the term *state* is used synonymously with the term *nation*, which is much different in that the latter refers to a people with a common identity. The meaning of *state* is also obscured because a state's first level of subdivision, commonly called a province, also

is sometimes called a state. The United States is an example where this occurs. However, its states (from Alabama to Wyoming) do not have sovereignty. The United Nations attempts to avoid this confusion by using a capital “S” for those with sovereignty and a lowercase “s” for those without it. This practice helps distinguish the two concepts but has not been widely adopted by others. In any case, the practice works only in some written languages and not in any spoken language.

The world’s political map generally consists of states. Yet among the world’s states are a number of political entities (e.g., colonies, protectorates) that do not completely fulfill the requirements of a state. Similarly, other political entities (e.g., intergovernmental and nongovernmental organizations [IGOs and NGOs]) also are confused with states because they share some characteristics with states. States are distinguished from these other political entities because they have all the required characteristics: government, sovereignty, territory, a permanent resident population, recognition, and organized economic, transportation, communication, and public welfare systems. *Government* refers to an administrative system that oversees the functions of the state. It enacts and enforces laws, manages foreign affairs, regulates the economy, organizes defense, provides some degree of health care and universal education, and designs the transportation and communication systems and ensures their proper functioning. Sovereignty is the ability of a state’s government to perform these functions without interference from other forces, either internally or externally. Some political entities on the world map fail to meet these two criteria and consequently are not considered to be true states. Examples include Greenland (part of Denmark) and Puerto Rico (a territory of the United States with commonwealth status). Similarly, French Guiana (in South America), Guadeloupe, Martinique (both in the Caribbean), and Reunion (in the Indian Ocean) are considered to be among the 26 regions that constitute France as a state, while Clipperton Island, French Polynesia, French Southern and Antarctic Lands, Mayotte, New Caledonia, Saint Barthelemy, Saint Martin, and Wallis and Futuna are France’s dependencies.

Recognition is important for the long-term viability of states. When states have it, other states are expected to treat them according to international norms, most notably to respect their sovereignty and territorial integrity. Those without recognition are vulnerable to infringement on their sovereignty and territorial incursions and claims by other states. Examples of entities on the political map that claim statehood but are not recognized by other states include Nagorno-Karabakh (in Azerbaijan), Somaliland (in Somalia), and Transnistria (in Moldova). Others are only recognized by a very limited number of countries. For example, in early 2010, Abkhazia and South Ossetia were recognized only by Russia, Nicaragua, Venezuela, and Nauru, while Northern Cyprus was recognized only by Turkey. Some have greater recognition. For example, Kosovo and the Sahrawi Arab Democratic Republic (Western Sahara) were recognized by 64 and 49 states, respectively, by early 2010, while the Republic of China (Taiwan) now has fewer than 30 states that recognize it, as many others have shifted their recognition to the People’s Republic of China. Other states are recognized by most other states but still lack full recognition. For example, in early 2010, Israel had diplomatic relations with more than 150 others, and Palestine was recognized by 112, but neither country recognizes the other. Some states have almost complete recognition except by a few states. Examples include Cyprus, which is not recognized by Turkey, and North and South Korea, which do not recognize each other. Though greater recognition brings greater security, these latter cases also illustrate that states still are vulnerable to hostile neighbors that do not recognize them.

States function internally with either a unitary or a federal structure. Unitary states have centralized governments where the power of the state rests and decisions are made. Lower levels of government (e.g., provincial, county, and municipal) are simply nodes that convey and enforce the central government’s decisions and then relay information back to it. Nearly 160 of the approximately 200 states on Earth are unitary states, with France often cited as the best example. Federally structured states are decentralized, meaning that lower levels of government have some degree of

autonomy and frequently levy taxes to perform their separate functions. Federal states are structured either symmetrically or asymmetrically. For the former, all subunits within a layer of the governing structure have the same relationship and degree of autonomy with respect to the central government. The United States, Switzerland, Germany, Canada, and Australia are examples. In asymmetrical states, the relationship between the central government and each other governing unit varies according to what each subunit has negotiated with the central government. The United Kingdom, the Russian Federation, Spain, and Italy are examples. Some academics believe that federal states must be symmetrical and consider asymmetrical states a third type of internal structure: regional.

States can be divided into a number of types: city-states, empires, nation-states, and supra-states. A city-state comprises a single, dominant city that extends its authority over a hinterland, from which it obtains resources. City-states are small in size and trace their origins to the beginning of human civilization. Many of them emerged in fertile river valleys where agricultural surpluses supported sufficient population numbers to form cities. Examples of these river valleys are those found along the Nile, Tigris-Euphrates, Indus, and Huang He (Yellow). Other early city-states were found among the Greeks and in Meso-America and the Andes. Examples of modern city-states are Andorra, Liechtenstein, Monaco, San Marino, and Singapore.

The early city-states were absorbed into empires when they emerged and grew. In contrast to city-states, empires are large in size, with networks of cities. While culturally akin peoples, such as the ancient Greeks, created numerous city-states, empires included many diverse peoples within their boundaries, though they usually were founded by a single people. The early empires were built by peoples such as the Romans, Persians, Mongolians, Chinese, Aztecs, and Incas. The legitimacy of emperors and the expansion of their empires were rooted in the belief that emperors either were divine or ruled by divine right. Empires dominated most of human history, with many lasting into the 20th century, most notably the British, French, Russian, Ottoman, Chinese, and Japanese empires. Some argue that the Soviet

Union was an empire and that contemporary Russia and China retain the characteristics of empires. In addition to their cultural diversity, empires were usually asymmetrical in their governance structures. Empires typically allowed the peoples they conquered and incorporated into them to retain some of their traditional laws and governing practices.

In the 17th century, the modern state began to emerge. Until this time, dynasties typically ruled the states, with the state being treated as a family possession by members of the controlling dynasty. Monarchs usually saw themselves as above the law, which they often applied capriciously, albeit within a cultural context. Consequently, interstate relations, including alliances and the waging of war, were conducted according to familial interests, with states treated as instruments for promoting and protecting dynastic interests. This situation began to change after the Thirty Years' War (1618–1648), which witnessed the excesses of this state system. The resulting Treaty of Westphalia (1648) sought to limit the consequences associated with monarchs' treatment of their states as personal possessions. It established modern international practices such as the use of formal diplomatic connections, alliances, and rules for war and peace. It included the idea of "just war," earlier advocated by Hugo Grotius, who argued that the only valid reasons to initiate war were for defense, inflicting punishment, and obtaining something that rightfully belongs to or is due to the aggrieved party waging war. In curtailing the personal agendas of monarchs, the Treaty of Westphalia forced monarchs to increasingly justify their actions in the interest of their states. These newer views and practices established the modern state system, which is frequently called the Westphalian system.

The modern state crystallized in the 18th century with the Enlightenment, which also marked the rise of the modern nation. The two fused together into the nation-state as the state replaced the concept of monarchy with the concept of nation to justify its existence. Similarly, the nation turned to the state to protect, preserve, and cultivate itself. The 19th century became known as the age of nationalism and is characterized by the reorganization of empires into nation-states. This process continued in the 20th century, which

was marked by notable events leading to the creation of new nation-states: the Paris Peace Conference at the end of World War I, the decolonization that took place after World War II, and the dissolution of the Soviet Union, Czechoslovakia, and Yugoslavia following the end of the Cold War in the 1990s.

In the aftermath of World War II, a new supranational idea emerged that exists alongside the concept of the nation-state and eventually may supplant it. The supranational consists of three or more states working toward some degree of integration of their functions. Because it is a new phenomenon, the degree of integration is still not clear. The European Union (EU), which began with 6 and now has 27 member states, is the most advanced example of a supranational. The initial coordination of economic policies was followed by similar coordination of social and political policies. A clear and recent example of this cooperation was the creation of a common currency, known as the *euro*. Over time, the EU also has created executive, parliamentary, and judicial institutions to manage its shared functions. Supranationals such as the EU may seem little more than transitional entities that only exist while smaller states merge into much larger ones. However, the idea of the supranational is not simply to create giant nation-states. On the contrary, nation-states remain distinctive and autonomous units within supranationals. In the case of the EU, some member nation-states opt out of many practices and policies, including the use of the *euro*. Similarly, national identities are not intended to merge into a new, single, homogeneous supranational identity. At the same time, the ideal level of integration has not yet been determined for supranationals. In the case of the EU, many of its inhabitants fear that integration may erode their distinctive national identities.

STEEL INDUSTRY, GEOGRAPHY OF

Today, the geography of the steel industry is marked by remarkable internationalization rather than being bound by nationalist industrialization programs for domestic development. The industry's ascent was concomitant with the Industrial Revolution in the 19th century. As the demand for railroads, machinery, and industrial infrastructure emerged, the growth and location of the industry in Britain, and later the United States as

well as other European countries, were dictated by the availability of raw materials. With technological changes and state intervention, the geography of steel production witnessed significant movement away from raw materials and national markets to increasingly global markets and off-shore production. With neoliberal policies, the industry is characterized by more international trade, foreign direct investment, mergers and acquisitions, and, unexpectedly, the predominance of entrepreneurs and firms from developing countries. More recently, as a result of rising energy and raw material costs, the geography of the industry is on the threshold of another round of spatial reorganization.

Raw Materials and Geography

At its core, steelmaking is a relatively simple process. Iron ore, sinter, coal, limestone, and small quantities of scrap are fed into a blast furnace to produce pig iron, which in turn is charged into a basic oxygen furnace to produce molten steel. Liquid steel is then combined with other elements and cast into various shapes, sheets, and sizes, depending on the final application. From the 19th century until the 1950s, most steel plants were located near raw material sources. Historically, coal and/or iron ore regions have hosted steel mills—notably the English Midlands, Western Pennsylvania in the United States, the Ruhr in Germany, Lorraine in France, Minas Gerais in Brazil, Northern and Eastern China, Eastern India, and Eastern Australia. In some cases, national security and regional development concerns have influenced the location of mills away from vulnerable border areas.

However, with technological change, diversified markets, and declining transportation costs, steel mills are no longer tied to the sources of raw materials. With revolutionary changes in transportation and material-handling technologies, a new kind of coast-based steel mill emerged, allowing the efficient sourcing of high-quality coal and ores by massive ocean-faring vessels from far-flung mines in South Africa, Brazil, Australia, India, and so on. In addition to importing raw materials, port-based mills also facilitated competitive exports of steel products, resulting in gains from economies of scale. East Asian

countries, owing to the lack of raw materials, adopted such an investment strategy, which was later followed by other late-industrializing countries. Most Japanese mills, the Pohang Iron and Steel Company (POSCO) in South Korea, China Steel in Taiwan, Companhia Siderúrgica de Tubarão (CST) in Brazil, and Rashtriya Ispat Nigam, Ltd. (RINL) in India are all deepwater-based mills. Integral to the industrialization strategy, these states targeted the steel industry through state ownership (Steel Authority of India, Ltd. [SAIL] in India, SIDERBRAS in Brazil, and POSCO in Korea), investment, and pricing policies for domestic development and exports.

Technology and Geography

The entry barriers to integrated steel production based on coal and iron were high. The main bottleneck was investment, running into roughly US\$10 billion for a 10-million-ton annual capacity state-of-the-art plant. Only enterprises with deep pockets or access to public resources, such as state-owned steel companies, could venture into such large-scale operations. This led to the development of minimill technology, which had a smaller scale of operations and eliminated the expensive coke ovens and blast furnaces used in integrated production. Minimills use steel scrap as raw material, which is converted to purified molten steel using electric arc furnaces (EAFs). Earlier, small quantities of high-value specialty steel products were produced with arc furnaces. The refinement of minimill technology through the use of high-quality (recycled) steel scrap in high-income countries such as the United States, the lower investment barriers due to the small scale of operations, and the advances in casting technologies for minimills to produce high-quality steel sheets for the automotive industry changed the geography of the steel industry, especially in the United States.

As the American South had scrap, low-cost electricity, and land, it became a magnet for many greenfield minimills. In the 1990s, many such mills were constructed, with Nucor, an American firm, leading the pack. Importantly, the rural South allowed the new minimill companies to be geographically removed from major urban centers and the trade union activities common to the

Bethlehem graveyard and steel mill, Pennsylvania

steel and automotive industries in the industrialized North. Weak unions meant more flexibility in shop floor practices, the elimination of strikes, and lower labor costs. The new minimills were instrumental in instituting a flexible work culture, with bonus payments in lieu of the standard fixed employee benefits as part of the total compensation package. Additionally, nontariff barriers, such as the voluntary restraint agreements imposed by the Reagan administration on steel and auto imports from Japan, and the appreciation of the Japanese yen compelled many Japanese auto producers to locate manufacturing facilities in the Southern United States. Not coincidentally, many Japanese steel producers also

formed joint ventures with American steel companies to produce high-quality flat products for both American and Japanese auto transplants. In this sense, the supply response emanating from the American minimill segment and government policy led to a decentralized industry structure.

The geography of the industry was subsequently shaped by breakthroughs in both minimill technology and other small-scale production innovations. Japan and South Korea, best known for energy-efficient, large-scale integrated production, began adopting such technologies. In the 1990s, Tokyo Steel, Hanbo of South Korea (now under new ownership due to bankruptcy), and Essar and Jindal in India entered the fray with

In this astronaut photo from June 12, 2009, the urban fabric of Pohang, South Korea, is strikingly divided by the Hyeongsan River. To the west of the river, residential and commercial development is characterized by small-footprint, gray- and white-roofed buildings. The eastern side of the river is dominated by industrial development associated with the Pohang Iron and Steel Company steelyard. This development (*center*) includes large factory and storage buildings with striking light blue and light red rooftops.

new technologies due to smaller production capacities and thus lower investment costs. As scrap prices increased due to expansion in mini-mills, alternative raw materials were developed. These were directly reduced iron (DRI) and hot briquetted iron (HBI), made feasible by inexpensive natural gas and coal. These inputs are a purer form of iron, which can be fed into blast furnaces and EAFs to produce higher-quality steel. Similarly, the COREX process using noncoking coal (thus doing away with large blast furnaces) permits the direct charge of molten iron into EAFs. These innovations, with their small-scale operations, have been suitable for firms in developing countries with access to natural gas and with

limited markets. In India, Essar Steel, with captive offshore gas sources, has integrated backward to DRI, while Jindal has adopted the COREX process. Other companies from Asia and Latin America have also adopted these small-scale technologies to produce high-quality steel.

Globalization and the New Geography

In the wake of the global economic downturn in the 1970s, the neoliberal ideology of free markets in the 1980s was widely pushed across the global economy. Individual governments, voluntarily and otherwise, internalized deregulation, pursued liberal economic policies, and attempted

privatization of state firms. In this environment, the steel industry witnessed considerable upheaval. Declining steel production associated with the falling significance of heavy industry and a growing services sector led to deindustrialization in the advanced capitalist countries. The simultaneous pursuit of state-led industrialization in select developing countries such as India, China, Brazil, and South Korea had already altered the structure of global steel production. However, many state-owned enterprises, including those in the former Eastern Bloc countries, were plagued by financial and technological inefficiencies, which made them good acquisition targets for investors. The Soviet Union had been the world's largest producer, but its breakup in 1991, combined with the challenges of market transition, reduced steel output in Russia significantly. Furthermore, deregulation, privatization, and new opportunities under global economic integration generated new competitive dynamics in the geographical dispersion of the industry.

Previously, steel industries were seen as national projects, designed to contribute to self-sufficiency in production and targeted at domestic consumption. With deregulation and technological developments, the internationalization of the industry was imminent, leading to a new geography. There are several interrelated forces that led to international investments and increased trade in the industry. First, entrepreneurial firms began to invest in new minimill technology and acquire weak state-owned firms. Second, some of these purchases were integrated backward to raw material production, which was made easier with the discovery of natural gas in certain locations. Third, entrepreneurs and steel firms from developing countries, especially India, have invested and acquired foreign steel and steel-linked raw material production units such as DRI. Fourth, as both China and India continue to grow economically, sustaining the demand for basic steel products, many foreign companies, such as POSCO from South Korea, are investing massively in iron ore as well as steel manufacturing plants in India and elsewhere. Finally, as the demand for raw materials increases due to high economic growth in China and India, these countries have aggressively pursued investments in and alliances with the mineral-rich countries of Africa and Latin America.

The best-known case of internationalization is Mittal Steel. Lakshmi Mittal, hailing from a trading family in India, purchased an old steel mill in Indonesia and built his steel empire in the 1980s and 1990s. He acquired financially strapped, private- and state-owned mills in rich and poor countries such as the United States, Canada, Germany, Ireland, Kazakhstan, Mexico, and Trinidad. He also strategically purchased DRI plants and integrated steel production backward. Perhaps the biggest and the most controversial acquisition has been Arcelor, a large European firm, which itself was the result of earlier mergers. The French, Spanish, and Luxembourg governments strongly opposed the takeover by Mittal, but in the end, the merger went through with a price tag of \$26.5 billion, making the new ArcelorMittal the largest steel company in the world, with nearly 120 million tons of annual capacity and 320,000 employees worldwide. Nippon Steel of Japan, at one time the world's largest steel company, stands at number two, with about 33 million tons production capacity. After this merger, the U.S. government compelled ArcelorMittal to sell off its U.S. plant at Sparrows Point in order to reduce its perceived monopoly.

Other steel companies, such as Essar Group from India, also strategically integrated backward to DRI production. Supported by a captive natural gas supply, DRI-based production expansion made good sense. Essar also pursued a similar global acquisition strategy. It obtained a steel mill in Canada and a mine in Minnesota in the United States, constructing greenfield units in Vietnam and the Caribbean, and has immediate plans for more acquisitions in the United States, Latin America, and Africa, especially in coal and iron ore. The Tata Group, a highly diversified family business, also expanded its steel operations around the world, including Europe, Vietnam, Singapore, and South Africa. But its biggest purchase has been the Dutch-British Corus Group, which was also the final result of earlier mergers, for a price of US\$12 billion. It also acquired Jaguar and Land Rover in the United Kingdom from Ford Motors. These purchases are driven by market access, while the purchases of mines and DRI-producing plants have been strategically aimed at ensuring raw material supplies.

With the high growth in the demand for natural resources due to the growth of China, India, and other emerging market economies, the earlier pessimistic view of “resource curse” has been tempered. Today, extractive industries are enjoying unusual terms of trade gains due to rising prices. Both China and India have begun aggressive and competitive overseas investment in oil and other natural resources in Africa, Central Asia, the Middle East, and Latin America. This development is likely to influence the future geography of the industry. Cash-rich companies from China and India, enjoying massive revenues from exports and inflows of FDI, could continue to purchase mines and steel mills to cater to growing domestic and global demands. This creates a historic opportunity for natural resource-rich economies such as those in Africa and Latin America to reduce their structural dependency and leverage their raw materials for basic industrialization. However, without the necessary institutional changes to mobilize foreign and domestic savings as well as marshal political and administrative capacity, it would be difficult to alter the spatial organization of the steel industry.

Additional macroeconomic factors could continue to shape the geography of the steel industry. While upward movement in the prices of resources can distribute global wealth, it could also have a dampening effect on final demand. The rise in the average price of oil is a case in point, which in early 2008 was close to US\$100 per barrel, rising from about US\$28 per barrel in 2001. With the global credit squeeze resulting from the U.S.-led subprime crisis, the demand for steel-intensive investments could be curtailed and thus their supply constrained. At the same time, nonfossil fuel-based vehicles as well as large-scale public transportation could witness new sources of global demand. However, as environmental concerns mount, rich countries will prefer to locate large-scale mills in raw material-producing, mostly poor countries. Consider the mineral-rich but impoverished state of Orissa in Eastern India, which has been targeted by Korea’s POSCO, India’s Tata, and the Indo-European MittalArcelor for large-scale investments in mining and steel units. The combined estimated value is \$22 billion. If not

checked, such massive investments are likely to have high human costs and ecological consequences. Alternatively, corporate social responsibility, stringent oversight, and new technologies and energy sources could further shape the geography of the global steel industry.

STEREOSCOPY AND ORTHOIMAGERY

If you place your thumb in front of you and then look at it with your left eye and then the right eye, what you will notice is that the thumb is “moving” in relation to the objects behind it. This phenomenon is what helps the human brain see depth and thus perceive which object is in front and

Figure 1 Relative photogrammetric accuracy versus angle of intersection

Source: Light, D. L., Brown, D., Colvocoresses, A., Doyle, F., Davies, M., Ellasal, A., et al. (1980). Satellite photogrammetry. In C. C. Salma, C. Theurer, & S. W. Henriksen (Eds.), *Manual of photogrammetry* (4th ed., pp. 1305–1369). Falls Church, VA: American Society for Photogrammetry. Reprinted by permission of the American Society of Photogrammetry and Remote Sensing.

which one behind. It is called *binocular vision*, and the displacement of your thumb is called *parallax*. The larger the parallax, the further our thumb is from the objects behind it. What we actually perceive is the parallax, and through this we see and appreciate depth. However, it would be wrong to think that all human depth perception comes from the parallax. There are many more cues, such as shading, relative size, precedence, contrast, and haze, that work just fine with *monocular vision*.

This impression of depth can be also realized with the use of images of the same object that are taken from different positions. When each of a pair of such images is separated and viewed by each eye separately, it is possible to perceive depth. This is called *stereoscopic vision* or *stereo-vision*. There are many ways to project the images to each eye, such as through anaglyphs (“filtering” the images with the use of blue-red display and glasses) or polarization (“filtering” the images

with the use of vertical and horizontal polarization display and glasses) or other methods that are used in modern stereomonitor. This pair of images is called a *stereogram* or *stereopair*. The science or art that deals with the use of binocular vision for the observation and production of stereograms is called *stereoscopy*.

The average distance between the human eyes is about 65 millimeters. The human brain can differentiate (perceive parallax) between two objects when they are at a minimum angular distance of about 15 inches. With the use of simple triangulation, we can estimate the minimum depth distance judgment according to the distance of an object from the human eyes. The further the object is from our eyes, the more difficult it gets for us to judge its depth distance. If, however, we can somehow increase the distance between our eyes, then we would get better depth perception, and thus, the distance of the object could be better estimated (Figure 1).

The distance between the two images of the object is called a *baseline*, and the larger it is, the less the error of the object positioning and thus the more accurately the depth distance is calculated (assuming that the other parameters are the same).

As photogrammetry concerns itself with the geometric measurements of objects in analog or digital images, the stereoscopic measurement principle is directly applied. With the production of images of the same object from two different places in space (stereoscopy), one could make measurements of the object's depth distance. This way, the recording and measurement of the object are done in the three-dimensional (3D) world and not just in the 2D world of a piece of paper or a computer monitor.

However, it becomes challenging when we need to represent or display the object. The problem lies in the way the camera is operating. The photograph is captured through a perspective center (single-point perspective view), and the object does not have the same horizontal distance on the plane and on the photograph. In other words, the photograph is not an orthogonal representation of the object. The relief of the object is introducing an error in the measured distances on the photograph. For this, there is a need to use stereoscopy so as to produce a stereopair and thus be able to measure the relief of the object. By knowing the depth distances, it is easy to "project" the object onto a 2D surface, but this time, all different points on the surface have the correct horizontal distances. This photogrammetric product is called *orthoimagery*.

Orthoimagery consists of representing an object in the same way that a map does. This allows us to use orthoimages just as we would maps and thus make direct measurements. But while the map displays selected information that the cartographer chose, the orthoimagery displays all the details of the object that could be captured at the moment. However, it is an artificial product, totally computer generated. Its precision depends greatly on the parameters of image acquisition (orientation of the image, spatial position of the camera) and the relief (acquired by the stereopair).

STORPER, MICHAEL (1954–)

One of the discipline's leading economic geographers, Michael Storper is well known for his rigorous interrogations of the spatiality of capitalism. His work lies at, and has forged, the intersections of economic development, technological change, innovation and creativity, trade, globalization, and the political economy of regions.

A doctoral student of Richard Walker at the University of California, Berkeley, Storper began his career in the School of Urban and Regional Planning at the University of California, Los Angeles (UCLA) in 1982, and he continues to be affiliated with the School of Public Affairs there. From 1996 to 2002, Storper served as a professor of sociology at the University of Marne-la-Vallée, France, and continues as a professor of economic sociology at the Institut d'Études Politiques de Paris. In 2004, he assumed a Centennial Chair in Economic Geography at the London School of Economics (LSE), but he divides his time between the LSE and UCLA. Storper is thus an important intellectual on both sides of the Atlantic Ocean and writes in both English and French. His papers and books have been noted for their theoretical sophistication and ability to draw together diverse topics and lines of thought,

both traditional and contemporary, into elegant syntheses.

Storper's works have long been important in several subject areas of economic geography. His earlier papers, for example, offered stinging critiques of the product cycle as simplistic and unidimensional. *The Capitalist Imperative*, coauthored with Walker in 1989, marked a foundational summary of economic geography in light of the rising prominence of Marxism and the centrality of the division of labor. In the 1980s, Storper played a key role in the formation of the informal "Los Angeles School" of urban analysis, which paved the way for understandings of economic landscapes in light of the emergence of post-Fordist complexes of flexible production. His work was central, for example, to the emerging conceptions of how and why firms adopted new technologies; their relations to uncertainty, transaction costs, and economies of scale and scope; and how labor markets fluctuated in response. Empirically, he analyzed, among other things, the U.S. film industry and its locational dynamics.

By the 1990s, Storper's career led him toward systematic understandings of the dynamics of regional change more broadly, particularly the contingent trajectories faced by different types of places as they grappled with the changing constraints and opportunities generated by the global division of labor. In *The Regional World*, which appeared in 1997, he sketched a view of a world economy dominated by a necklace of world city-regions, in which agglomeration economies facilitate processes of creativity and innovation. He also took into account issues such as different forms of institutional organization, flows of knowledge, patterns of decision making, regional convergence and divergence, and the spatial scales at which varying social and spatial processes operate to lay out several possible "worlds of production." He offered comparative analyses of regions in Western Europe, the United States, and Brazil. More recently, he has turned to the role of "buzz," or dense webs of face-to-face contact for the exchange of tacit knowledge among key actors as mechanisms of regional competitiveness and innovation.

STRABO

(ca. 58 BC–ca. AD 24)

Strabo, born in Amaseia, was a Greek historian and philosopher and one of the most important ancient geographers. As the author of *Geographica*, a 17-volume treatise that has come down to the present almost complete and is a fundamental source of information on the history of geography and cartography of that period, he

played an important role in the development of early geography.

The treatise offered a historical-anthropological frame and aimed to be a useful cultural instrument for Strabo's rulers. Strabo wrote it not only on the basis of the work of his predecessors (e.g., Anaximander, Eratosthenes, Hipparchus) and taking into account the epic poems attributed to Homer but also incorporating his own ideas and personal observations. Strabo founded his knowledge not only on abstract concepts but also on the concrete experiences gained through his travels and the relations he built with different populations and their cultures, approaching area studies in a sense that could be defined as an early form of "geopolitics" and "human geography."

According to Strabo, geographic studies cannot neglect philosophy, mathematics, geometry, or astronomy and cannot retreat from natural, historical, and economical aspects in the analysis of a region. Explaining the links that exist between a people and their natural environment, he underlined, for instance, the importance of the sea in the evolution of civilization, particularly as can be seen in the case of Greece.

Strabo gives an interesting description of the known world of the time, imagining the inhabited portion of the Earth to be less wide than that considered by Eratosthenes and different from that pictured by the Greek sailor and geographer Pytheas. Strabo set the northernmost edge of the *ecumene* (the world's habitable zones) on the parallel through Ireland, beyond which there was a perpetually frozen region. He set its southern limit at the parallel crossing Ethiopia and its western and eastern limits at the Pillars of Hercules and the mountains of Northern India, respectively. Evocative descriptions are provided regarding the shapes of lands such as the Peloponnese, which he said looked like a leaf, and Mesopotamia, which he compared with a boat seen from its side. Among the many subjects dealt with in his writing are the Mediterranean Sea and the populations living on the lands washed by it, the source and the delta of the Nile River, and the geography of Germania and its tribes.

STRAHLER, ARTHUR (1918–2002)

Arthur N. Strahler earned his doctorate in geomorphology at Columbia University, emerging in 1945 as a classically trained Davisian (read qualitative) geomorphologist. However, his personal dissatisfaction with this kind of geomorphology was soon fueled by exposure to the seminal work of Robert Horton. During the 1950s, Strahler was a great pioneer of quantitative geomorphology founded on physical and chemical principles. His influence was greatly extended by the impact of his doctoral students, including Richard Chorley, Donald Coates, Marie Morisawa, and Stanley Schumm.

Influential Pioneering Papers

Strahler produced a profoundly important series of papers. Initially, he introduced extremely simple statistical measures such as tests of significance, but sophisticated concepts such as dimensionless numbers (e.g., stream order, relief ratio, and the hypsometric curve) quickly followed. Dimensionless numbers were a critical contribution that permitted comparisons across many scales and produced insights previously masked by the shadow cast by scale differences. Perhaps the single most famous concept, among many, is the "Strahler order number."

Within the Strahler stream-ordering system, a stream without tributaries is designated a first-order stream; on meeting another first-order stream, the united streams form a single second-order stream. Beyond this, any stream can absorb those of inferior order, but when meeting a peer, the two unite to become a single stream of the next higher order. In turn, this concept may be applied to drainage basins and associated fluvial concepts. This idea is one of the few to escape geomorphology to become essentially universal throughout science. Appreciation of the role of statistical randomness eventually constrained such research. In short, Strahler introduced a set of “timeless” concepts that did much to redress the then prevailing historical, or time-bound, perspective of geomorphology inherited from Davis.

The Systems Concept

Strahler also made important contributions to the introduction of systems concepts into geomorphology. In particular, he placed a very heavy emphasis on appropriate dimensional analysis in the equations used in a systems approach such that they are always appropriately balanced dimensionally. He also advocated the use of symbols derived from basic electrical circuitry as the most appropriate icons for creating diagrams of system models.

The Earth Science Educator

Strahler spent much of his later career as an independent author, producing innumerable introductory texts in physical geography, geoscience, and environmental science. Within his last publications is a significant attempt to counter the modern challenge to the science of creationism, later renamed creationist science.

STRATOSPHERIC OZONE DEPLETION

Ozone, denoted chemically as O₃, is a relatively unstable gas with each molecule containing three atoms of oxygen. In a thermally stratified atmosphere, ozone occurs in the lowest two layers, the troposphere and the stratosphere, where it performs different roles. In the stratosphere, ozone occurs in large amounts over a deep vertical extent, forming the *ozone layer*. Stratospheric ozone is sometimes called “good ozone” because it absorbs some of the potentially harmful ultraviolet (UV) radiation from the sun, which can cause skin cancer and can damage vegetation, among other things. Ozone in the troposphere, particularly near the surface, is a secondary air pollutant, which, as a principal component of photochemical smog, is known to have adverse effects on the environment and human health. Stratospheric ozone accounts for about 90% of atmospheric ozone.

The amount of ozone in the stratosphere at any given time largely depends on the balance between the rates of production and destruction of ozone, which are controlled by factors including sunlight intensity, temperature, and the quantity of other gases involved in the ozone formation-destruction process. Ozone forms naturally in the stratosphere whenever UV sunlight is present. When high-energy UV radiation from the sun strikes an oxygen molecule, it causes the molecule to split into two free atoms, each of which combines with an oxygen molecule to produce an ozone molecule. Destruction of ozone in the stratosphere takes place as

Figure 1 EP/TOMS corrected total ozone for September 1, 2005

Source: National Aeronautics and Space Administration. (2007). *Total ozone mapping spectrometer*. Retrieved December 15, 2008, from http://jwocky.gsfc.nasa.gov/eptoms/ep_v8.html.

quickly as its formation because the chemical is so reactive. As ozone absorbs UV radiation, the molecule splits into one free oxygen atom and one molecule of oxygen. The free oxygen atom then collides with an ozone molecule to form two molecules of oxygen. These reactions occur continually wherever UV sunlight is present in the stratosphere. The net result is a reservoir of ozone that peaks at about 10 parts per million in the midstratosphere, between 12 and 25 kilometers in altitude.

The amount of ozone in a total column of the atmosphere is expressed in Dobson units (DU). A typical value for the ozone column is 300 DU. In the mid 1970s, data collected in the upper atmosphere first showed that the amount of ozone in the stratosphere had diminished. In recent years,

the Ozone Monitoring Instrument (OMI) onboard National Aeronautics and Space Administration's (NASA's) Aura satellite and the EP/TOMS (Earth Probe/Total Ozone Mapping Spectrometer) have been used to get a global picture of ozone levels. Analyses of data from these instruments show that except over tropical latitudes, stratospheric ozone depletion occurs across all latitudes, with the greatest depletion, representing the disappearance of up to 60% of stratospheric ozone, occurring above Antarctica in September, creating what is popularly called the "ozone hole." An example of global ozone data derived from EP/TOMS for September 1, 2005, is shown in Figure 1. Apparent from the image is the ozone hole over Antarctica, represented by a decreased ozone amount

Figure 2 Daily values of total column ozone derived from TOMS and OMI for different years over Antarctica

Source: National Aeronautics and Space Administration. (2007). *Total ozone mapping spectrometer*. Retrieved December 15, 2008, from http://jwocky.gsfc.nasa.gov/ep_toms/ep_v8.html.

ranging from about 250 to <120 DU. More detailed information about the ozone hole can be obtained from Figure 2, which is a plot of the daily values of the total column ozone derived from different instruments for several years over Antarctica (40° S to 90° S).

The loss of stratospheric ozone is attributed to ozone-depleting chemicals (ODCs) that have entered the atmosphere as a result of anthropogenic activities. ODCs are anthropogenic chemicals such as chlorofluorocarbons (CFCs), halons, carbon tetrachloride, methyl chloroform, hydrochlorofluorocarbons, and methyl bromide. At one time, CFCs were the most widely used propellants in spray cans. Today, however, they are mainly used as refrigerants, as propellants for the blowing of plastic foam insulation, and as solvents for cleaning electronic microcircuits. Because ODCs are chemically inert, when released into the atmosphere, they do not react easily and

can exist in the troposphere for several decades, entering the stratosphere through the mixing and transport processes of the atmosphere. When CFCs enter the stratosphere, the intense UV radiation breaks them down, releasing chlorine (Cl) atoms that react with ozone, starting chemical cycles of ozone destruction that deplete the ozone layer. When other ozone-depleting substances such as methyl bromine and halons are broken apart, they release bromine atoms, which are several times more destructive to ozone molecules than Cl atoms.

One of the frequently asked questions about the ozone hole is “Why does it form in the South Pole, considering the year-round, relatively low sunlight intensity in the region?” This highlights the paramount significance of other factors for the severity of ozone depletion in the southern pole. It has been demonstrated in the past decade that these factors are a combination of conditions

that are unique to the area, such as the presence of the stratospheric polar vortex and the very cold temperatures in the winter months producing polar stratospheric clouds (PSCs). For most of the year, the halogen atoms in the polar stratosphere occur in forms such as hydrogen chloride (HCl) and chlorine nitrate (ClONO₂), which do not react with ozone or each other. However, as PSCs are formed in the polar stratosphere, they provide surfaces for activation of reactions that convert Cl compounds from relatively inert forms to reactive species that destroy ozone in sunlight.

STRIP MINING

Minerals located at or beneath the Earth's surface have long been used for building materials, energy sources, and a wide variety of products to further human development. There are numerous methods for mining these materials. Strip mining is one such method, which has proven to be efficient, economical, and, at the same time, controversial.

Strip mining is part of a broader category of mining techniques known as *surface mining*. These techniques, such as open-pit mining, quarrying, or high wall mining, involve moving massive amounts of earth from above the desired material. The rock, soil, and other material that cover the minerals are known as *overburden*. Each type of surface mining has methods in place to remove the overburden and, in some instances, to reclaim the site after mining operations are complete. Other than surface mining, rock and minerals are extracted from the Earth through underground mining, whereby shafts are dug into the seams, where valuable material is mined and then brought to the surface.

Most societies have engaged in extracting resources from the Earth for hundreds if not thousands of years. However, modern strip mining can trace its roots to the Industrial Revolution and the development of steam-powered, earth-moving equipment capable of removing large amounts of overburden. These early machines have evolved into massive excavators, such as draglines and bucket wheels, which rank among the largest machines ever built. Today, the United States and Germany, two of the most prolific strip-mining nations, lead the way in developing the technology for the machinery and infrastructure to facilitate these macroscale mining operations.

Strip mining occurs in numerous regions other than the United States and Germany. Resources are extracted by strip mining throughout Canada, India, China, Russia, Indonesia, South America, and Africa, among other locales. Energy resources such as coal and oil shale are often extracted through strip mining, as also other resources such as copper and iron ore. Strip-mining techniques are used worldwide for several reasons. Strip mining is highly economical because it requires far fewer workers than underground mining and because it generally is a shorter-term investment,

allowing mining companies to move more quickly onto other operations. Also, strip mining is safer for workers than underground mining because of the hazards associated with the latter, such as cave-ins, explosions, and respiratory problems such as black lung disease.

Traditionally, there have been two types of strip mining. The first is suited for flatter mine sites and is known as *area stripping*. This method places the extracted overburden from the strip currently being mined into the neighboring strip mined previously. The second version is termed *contour stripping* and is applied to areas that are hillier. Both methods are used in extracting coal, the mineral most associated with strip mining. For years, strip mining of coal in the United States was confined to the flatter areas of the Midwest and West, most notably the Powder River Basin of Wyoming. Mining companies in coal-rich Appalachia were not able to take advantage of the economical methods associated with strip mining until the development of a different type of strip mining called *mountaintop removal*.

Mountaintop removal coal mining is an adaptation of strip mining for use in mountainous areas. To gain access to the coal seams in Appalachia, the tops of the mountains must be removed by blasting, creating a flat area suited for strip mining. The use of strip mining in Appalachia has grown significantly since the 1980s due to the adoption of this controversial technique. Coal companies have benefited greatly from mountaintop removal, and it is considerably safer for miners than underground mining.

Mountaintop removal has also been extremely controversial in the region because of its environmental, health, and social effects. This form of strip mining is highly destructive to the local environment, due in large part to the practice of valley filling, where the overburden is pushed into the surrounding valleys as the mountaintop is flattened in preparation for mining. Creating valley fills has led to the contamination of many streams and has been the cause of numerous flash floods in Appalachia. Mountaintop removal sites are often not reclaimed to proper standards, which threatens biodiversity and the growing regional industry of ecotourism. Opponents of the practice also point to increased numbers of respiratory diseases caused by blasting debris, higher than

normal cases of autism and other developmental issues, and contaminated water wells.

Strip mining, including mountaintop removal, is regulated by the U.S. government. Numerous government organizations, such as the Office of Surface Mining Reclamation and Enforcement, the Environmental Protection Agency, and the Mine Safety and Health Administration, regulate mining practices to best ensure the safety of the workers involved as well as the surrounding environment and communities. The Surface Mining Control and Reclamation Act of 1977 is the most well-known policy that oversees strip mining. The policy regulates active mine sites and establishes guidelines for reclaiming abandoned strip mines.

While the U.S. coal industry is dominated by a few very large companies, numerous subsidiaries have been created as a way around regulations such as the 1977 legislation. Instead of reclaiming sites, the smaller subsidiaries file for bankruptcy, and the cost of reclamation gets absorbed by the state. The results of these activities can be seen in the numerous unreclaimed mine sites throughout the United States.

Strip mining remains a highly used but controversial method of resource extraction. In terms of coal, efficient strip mining is seen as a domestic solution to growing energy needs. Strip mining for other minerals remains popular because of the high rate of economic return associated with the practice. However, heated debates rage on, both domestically and internationally, questioning whether or not the benefits of the extraction method outweigh its numerous costs.

STRUCTURAL ADJUSTMENT

As an approach to macroeconomic reform in poor and middle-income countries, structural adjustment became a standard in lending programs of the International Monetary Fund (IMF) and World Bank in the mid 1980s. As an idea, it encapsulates the so-called Washington Consensus among these institutions and the relevant departments of the U.S. government (e.g., the Treasury, the Agency for International Development), all based in Washington, D.C. Following major national defaults throughout the developing world in 1982, these lenders implemented stricter conditions for disbursing funds, requiring debtors to “adjust” the “structures” of their economies. Principally, this move entailed scaling back both state regulation of financial markets and subsidies for key industries (e.g., manufacturing) and utilities (e.g., communications, energy). The goal was to make indebted countries—in Latin America, Africa, parts of Asia, and eventually the former Soviet bloc—more economically dynamic and profitable and thus more capable of loan repayment. Such successful metamorphoses, however, have been fleeting (e.g., in The Gambia, Thailand, and Argentina).

Adjustment moved countries away from import-substitution industrialization and similar regimes, which had shielded domestic economies from foreign competition and ensconced state bureaucracies as key providers of extensive public goods, toward a neoliberal model of more globalized markets and a more entrepreneurial role for the state. Despite the aim of “adjusting” poorer economies to converge on an ideal of development, in many cases, this shift intensified the differences between countries, cities, and neighborhoods.

Reforms

Every program of structural adjustment is nationally specific because debtors must negotiate individually, rather than as a cartel, with the key international financial institutions. Each “adjustee” is further distinguished by its own population, resources, political legacy, and cultures. Nonetheless, there are general features of reform that transcend adjustment cases.

In finance and trade, the fundamental prescription has been liberalization: the partial or complete removal of barriers to transnational capital and goods. For financial markets, there is loosening of rules for foreign participation in domestic banks and stock markets. Currencies are also primary targets, typically opened to market fluctuation to create more transparent management but sometimes pegged to another marketized currency (e.g., the Argentine peso, fixed to the U.S. dollar from 1991 to 2001). Trade, on the other hand, is affected by dropping tariffs on imported goods, which had indirectly subsidized domestic producers. Simultaneously, reduction in direct government subsidies to indigenous industries ended the official monopolies or direct ownership by the state. There have been many cases of other curtailed subsidies on basic consumer goods, particularly food—an austerity that, although considered imperative in some adjustment programs, proved an extremely volatile reform across all world regions.

For the state itself, there are usually two major forms of restructuring. The first is privatization of state-owned enterprises, which tend to be concentrated in basic utilities, from the post office to railways to water supply to telephones. There are many cases where privatization brings greater efficiency and some improvements in access to these goods, but it also can lead to steep increases in prices because these companies must operate using market logic, with demand possibly far outstripping supply and competitiveness—not well-being—taking foremost priority. Another drawback of privatization is that it can fail to break effectively with former monopoly conditions; without sufficient oversight, lucrative holdings can be distributed nepotistically at prices far below the market value. This has notably been the case with certain national airlines and phone companies (e.g., Zambia, Argentina). The possibility of extensive foreign ownership of local utilities—often considered strategic resources and part of the national heritage—is a feature of privatization that many critics also lament. The second major transformation to the state is decentralization, which shifts some functional and fiscal responsibilities away from national-level bureaucracies to provincial or urban authorities. Reductions in bloated federal governments

can result from this policy, but it has also backfired: Expensive redundancies can eventuate within state hierarchies, while sometimes local authorities gain new policy purviews and the right to set more independent agendas but without matching finances to realize them.

Repercussions

Beyond the shortcomings of reforms, there are also important unforeseen repercussions resulting from structural adjustment. An original adjustment aim, especially in African cases, was to end the “urban bias” in national development; that is, the curtailment of state subsidies to urban employment sectors and reductions in food subsidies would make nonurban areas more attractive, hypothetically easing the rapid urbanization of the developing world. Instead, several cases show vast increases in unemployment and impoverishment in cities, without ending rural-to-urban migration. Partly, this is because no clear benefits accrued to rural workers in agriculture (as many international commodity prices have been in relative decline), so the pressure to exit the countryside remains. Simultaneously, there was some economic growth in cities as a result of adjustment, but it tended to be limited to certain sectors, especially advanced services and sometimes resource extraction (primarily petroleum related). This growth was insufficient to offset employment losses in industries and public utilities, let alone to absorb urban newcomers, but it did create rather spectacular, circumscribed wealth in the major cities of some countries (e.g., the Philippines, Côte d’Ivoire).

Drastically uneven economies in cities led to stark inequalities across neighborhoods. The developing world has long exhibited extreme gaps in income and quality of life, but structural adjustment greatly exacerbated the polarization and led to the juxtaposition of wealthy and poor areas. Brazil is a famous case in this regard, but examples could be cited from all regions of the developing world. Many observers argue that the sheer obviousness of urban inequality, coupled with the grinding difficulty of making ends meet among the disadvantaged in the wake of adjustment, has contributed to the massive increase in crime and violence across these cities.

The most glaring inequality created by structural adjustment, however, is between poorer and wealthier countries. Although several countries outside the developing world have incurred substantial debt in recent decades (e.g., the United Kingdom, the United States), they can appeal to different sources of financing that do not intervene in domestic agendas as adjustment does. Countries of the developing world do not enjoy the same creditworthiness and therefore fall short of full sovereignty over their development priorities in an age of adjustment. The IMF and the World Bank have made efforts to improve adjustment, especially emphasizing poverty reduction recently. Structural adjustment as an explicit technique has, in fact, incited so much ire from different quarters that it now appears less frequently in loan agreement terminology, though many of its principles remain, particularly in the strong conditions placed on debtors. As such, *adjustment*—under that name or another—still forces the policy options for countries in the developing world into a narrow range of possible actions approved by Washington-based development experts.

STRUCTURALISM

Structuralism was at first a theoretical stance and subsequently a movement in the social sciences and humanities, including geography. The origins of structuralism lie mainly in French thought dating from the period between World War I and World War II, although the underlying concepts of structure and system are much older. At first, structuralism was confined to the analysis of (usually nonphysical) social and cultural objects and events that convey meanings and perform functions of communication, and it examined these with a language model designed to analyze and determine their significance. Subsequently, it was also applied to the analysis of political systems, the organization of knowledge, and the structure and evolution of whole societies. Instead of seeking to explain these phenomena one by one, structuralism adopted a systemic approach, concentrating on the underlying structures that made these phenomena possible and gave them meaning. In most disciplines, it subsequently gave way to poststructuralism, with its concentration on deep description and interpretation. The aim of this entry is to outline the evolution of this set of ideas and to consider the ways in which it has had an impact on geography and related disciplines principally in the 1970s and early 1980s.

Tenets and History

A structuralist approach involves the identification of the structural elements of a functioning system and the interrelationships/rules governing the ways in which the elements can be put together to enable the system to function without regard to any specific material content. Any object is interpreted as a product of a combination of structural elements within a system. A simple example is the system of traffic signals, whose function is to manage traffic. In this case the structure is a set of red, yellow, and green lights that are illuminated in repeated sequences and afford the significative content of the system.

Modern structuralism originated in the study of language, where it proved remarkably successful. For structuralists, a language is a self-contained system, each element of which has its

particular place and its own relations to the other elements of the language. In this field, the elements of the system are words or the speech sounds and sign elements of which they are made up. The rules include the grammar governing the way words can be put together. Because a system of language has the functions of signification/meaning and communication, a language is also a system of signs. As a result, expression elements (the signifiers), such as sounds, sound images, and words, cannot be identified independently of their content, their meaning, or the concept to which they refer (the signified). What is more, a language is a system of interdependent elements in which the value of one element depends on the simultaneous presence of the others. A signifier considered on its own has a relation with its signified. In a system, it has multiple relations with other signifiers, of which the most important is the relation of difference: A signifier has a meaning as a result not of its association with a particular signified but of its difference from all other signifiers. This idea of difference is founded on the idea of binary opposites: Finding out what a word or sign is not involves comparing it with some other word or sign.

To these ideas, Noam Chomsky added the examination of the creative role of language. He argued that the structures dealt with in linguistics were for the most part surface structures. Underlying these surface structures were, he suggested, deep grammatical structures from which a vast range of surface structures can be generated. This idea enabled him to explain how speakers of a language can utter sentences they have never heard. It also suggested that the wide variety of surface structures may share the same deep structure and that this deep structure may reflect the workings of the human mind. This view contrasted sharply with empiricist accounts that grounded language in sense perception, although it is important to emphasize that these conclusions were derived from painstaking observation and analysis.

Out of this literature emerged the idea that systems of language have an underlying synchronic structure and that this structure can be studied independently of its sociohistorical context and the consciousness of actors. An additional premise was that this structure governs

diachronic/historical and geographical practices without the awareness of the actors.

The next important step was Claude Levi-Strauss's extension of the concepts of order and the methods of structural linguistics to communication (symbolic) systems in anthropology. Just as comparative studies of languages were composed of fragmented studies until the notion of language as a system was adopted, anthropological studies of communities of peoples were composed of largely separate studies until the idea of society as a system was adopted. At the root of this extension of structuralist ideas to anthropology was the idea that cultural phenomena are socially constructed, are frequently immaterial, are associated with meanings/symbolic values, and can be considered as performing the function of communication, permitting analysis with a language model.

In contrast to interpretative or humanistic social science, which also deals with objects imbued with meaning, structuralism sees itself as an objective science. It insists that explanation (rather than understanding) has specific features that reflect the particular properties of systems of representation (which make possible the specific meanings that enter human conduct and choices). It emphasizes the fact that the manifest phenomena it studies are characterized by variety. For structuralism, the identification of generative structures does not rest on empiricist methods of empirical generalization or correlation. This is because social acts that have observable resemblances can have quite different meanings depending on the social systems of which they are parts. As a science of objects of study whose very nature is to vary, structuralism defines itself in terms of the correlation of differences. In the case of anthropology, the idea was that structural characteristics reveal themselves only through examination of the differences among customs, myths, kinship systems, and so on. And as in the case of Chomsky's approach to language, the aim was to identify the structures (of which human societies may not be conscious) that underpin observed social relations.

Up to this point, the object of study in structuralist approaches consisted of phenomena that are meaningful and that are directly or indirectly a product of human minds. In the 1960s, these ideas were extended to the study of social and political

phenomena to which a communication/language model was not applicable. A case in point was Althusserian Marxism. Other extensions were into the fields of literary and cultural studies (Roland Barthes), psychoanalysis (Jacques Lacan), and intellectual history (Michel Foucault).

Structuralism and Geography

The way in which these ideas entered geography was through a critique of its engagement with empiricism and in particular its encounter with structuralist Marxism. Geography had already passed through a quantitative revolution one of whose aims was to establish geography as a generalizing science, where science was understood in empiricist terms. Structuralism offered an alternative science model that sought to identify not what was common to surface phenomena but generative structures that gave rise to a great variety of surface phenomena: It offered an alternative route to the construction of theories to formulate and make intelligible the workings of the world.

In the 1970s, Marxism swept through the social and human sciences. In geography, many different strands of the Marxist tradition had significant impacts. Within the discipline, some of the most significant figures in this movement were not structuralists, yet strangely, critics of Marxism in geography chose to identify it with structuralism. Geography's engagement with structuralist Marxism was a result of the influence of the work of Louis Althusser, which itself entered geography largely through the early work of Manuel Castells in urban sociology. Castells's main interest was in the way social structures generate spatial structures: The analysis of spatial structures involves, he argued, an analysis of the way in which core elements of the social structure are spatially articulated (Table 1). For Castells, a society is composed of several modes of production, of which one is dominant. A mode of production is a combination of several systems of practices: economic, political, and ideological. In his framework of analysis, Castells identified four concrete spatial expressions (P, C, E, and M; see Table 1) of the fundamental elements of (relatively autonomous) economic, political, and ideological systems and the relations that organize them. In the case of an economic system, for

<i>Instances, Levels, or Systems of Practices of Social Structure</i>	<i>Relations</i>	<i>Spatial Expression</i>
Economic system	• Property (appropriation of product) • Real appropriation (technical labor process)	• P, Production: ensemble of activities producing goods, services, and information • C, Consumption: ensemble of activities relating to individual and collective consumption and reproduction • E, Circulation and exchange
Politico-institutional system	• Domination-regulation • Integration-repression	• I, Institutional segmentation of space • M, Administration and management
Ideological system	• Rationalization and legitimation of particular interests as an expression of general interest	• S, Symbolic space (signs, signifiers, signifieds): urban cultural forms as expressions of ideologies and ideological practices

Table 1 Social practices and spatial organization

Sources: Adapted from Althusser, L., & Balibar, E. (1970). *Reading capital* (B. Brewster, Trans.; pp. 125–127). London: New Left Books; Castells, M. (1977). *The urban question: A Marxist approach* (A. Sheridan, Trans.; pp. 212–216). London: Edward Arnold. (Original work published 1972 in French)

example, the elements are the factors of production (the laborer, the means of production, and the nonlaborer who appropriates surplus labor), and the relations between them (in a capitalist mode of production) are relations of property (the owner appropriates the product) and control (the owner organizes and controls the process of work). I, M, and S (see Table 1) were examined in similar ways.

This structuralist approach had both negative and positive features. On the negative side, it was believed to downplay the role of social action and social agency, although structuralist Marxists insisted that every social order is characterized by social conflicts and struggles. Individuals were, however, conceived as the occupants of positions established by structures, with little scope for effecting structural change. Althusser himself abandoned Marx's claim that the economy determined all other areas of life, arguing instead that the economic structure was determinant only "in the last instance." Although Althusser thereby rejected strict economic determinism, his variant of Marxism was still considered far too deterministic, as it rested on the existence of abstract structures and systems that determine social action

and social phenomena without working through the practical or cognitive understanding of actors. Although social scientists can discover these structures, actors are not necessarily aware of them.

On the positive side, it was clear that an explanation of the characteristics of particular places involves a synthesis of a multiplicity of practices, including economic practices that involve a set of relationships between people and their environment. A further advantage was that it afforded a common set/parallel sets of theoretical ideas (the concept of a system and of structures) that helped reduce the degree of fragmentation of geography, just as it had reduced the degree of fragmentation in other fields (comparative linguistics and comparative ethnology).

For that reason, the equation of Althusserian Marxism with determinism did not lead to a simple abandonment of structuralist ideas. Instead, it gave way to an alternative grammatical account of structures. On this account, structures are sets of rules and principles that govern social life and structure the possibilities of human action and interaction. Structures and systems function, however, because they are captured in the cognitive processes and the practical understanding of

social actors. What is more, these structures do not just govern social action. They themselves are socially constructed and are constantly reaffirmed and re-created in and through social action. Structures condition and result from action.

STRUCTURATION THEORY

Structuration theory has been a popular conceptual framework for studying social and spatial behavior since the 1980s, when it was initiated by the famed British sociologist Anthony Giddens. Geographers and planners with their own substantive theories about human behaviors have been able to think of the structures enabling or constraining those behaviors and, correspondingly, the behaviors that manifest those structures. This entry reviews the geographical and planning applications of the theory, after introducing structurationist thinking with an example.

Essentials

Structuration theory essentially surmounted the long-standing division in the social sciences between “micro” approaches, which focused on the behavior of individual human beings (e.g., the humanistic schools of thought), and “macro” approaches, which emphasized social structures and relations at the expense of an understanding of the human subject (e.g., structural Marxism). Structuration recognizes that human beings are sentient, knowledgeable agents; that is, they always possess consciousness about themselves and their world, however limited. This view depicts culture as the bodies of knowledge that people take for granted—that is, common sense, which allows them to negotiate their way through everyday life. Structures consist of the rules and resources that are drawn on in everyday life, simultaneously enabling and constraining human actions. In everyday life, actors draw on structural rules and resources, and in so doing, they reproduce those structures. Therefore, the socialization of the individual and the reproduction of society and place are two sides of the same coin. In everyday life, people reproduce the world, largely unintentionally, and in turn, their social structures reproduce them through socialization. In forming their individual biographies, people re-create and transform their social worlds. Thus, human beings are both produced by and producers of their worlds in time and space. History and geography are therefore continually produced through the dynamics of everyday life, the routine interactions and transient encounters through which societies are reproduced. For Giddens, the stretching of human activities across time and space is fundamental to the exertion of power. This process Giddens calls time-space distanciation, which geographers have called time-space convergence or time-space compression.

Structurationist Thinking About a School Closure

An example involving closure of a school can be helpful in explaining structuration theory. Begin thinking as a structurationist would by imagining how you would react to an announcement that your neighborhood school is closing, something

that has now happened so often in Western societies that most people have had this experience or know someone who has. Core structuration concepts sensitize a researcher to how people could or did act in general, that is, on an ontological level. In this example, application of structuration theory can help us interpret the effectiveness of residents who attempt to prevent school closures. Note therefore that structuration theory is a “second-order” theory and does not prescribe a specific course(s) of action in this particular situation. Consequently, with this and similar research applications, a supplementary “first-order” substantive theory is required for explaining, for example, why schools close and why residents get upset.

Actors

From the perspective of structuration theory, a neighborhood resident in this example is a social agent or actor who thinks about the closure of a school in his or her neighborhood, and thus, he or she will be reflexive about it. Residents may reflect from within their “practical consciousness” about how they should have reacted earlier to social trends culminating in declining student enrollments. Moreover, they will be able to share their feelings about the closure with friends and neighbors, from within their discursive consciousness. They may be sad or angry about its negating a period of childhood and thus threatening personal “ontological security.” Even an ex-resident who lives many miles away, or, in the lingo of structuration, is “time-space distanciated,” may think as an absent, as opposed to a present, actor about contacting residents or the authorities to fight the closure.

Structures

In structuration theory, social actors who reflect on what they do, and what others do, will activate structures that have entered into their understanding about ways of acting or not acting. These structures not only are the accepted rules of social behavior but also may provide concrete resources for actions. For example, parents and guardians have “authoritative resources” enabling their involvement in their children’s education as a reward for meeting their legal obligation to educate them. Taxpayers have “allocative resources”

through financially supporting their own school district instead of another one. Nonetheless, most residents fighting a school closure will be constrained in their involvement by the procedural rules for a review.

Duality of Structure

Most important in structuration theory, these actors exist in a duality with their rules and resources. It is difficult to know where to break into this duality, but in the school closure example, the previous actions of school administrators and residents will have created and routinized the accepted rules and resources for their respective use in making a closure decision or fighting it. Then, these social actors will internalize, use, and refine what they judge to be the most useful of these rules and resources in their actions. While doing this, they unintentionally reaffirm these rules and resources and therefore reproduce social relationships within the particular situation. For example, residents’ criticisms as well as administrators’ preferences will be behind an evolution in the procedures for closing a school from a committee-based process to a corporate business model. Also, for example, if school closures are progressively construed as only affecting students and their parents and guardians and not other neighborhood residents, then the aforementioned authoritative resources of parents and guardians will be their most powerful ones.

Two Versions of Structuration Theory

Anthony Giddens is the author of the version of structuration theory in the school closure example. During the same period, Pierre Bourdieu, a French sociologist, wrote an independent version of the same theory but with an altered relationship between actors and structures. Recent applications of Bourdieu’s core concept of *habitus* have revitalized explanations of gentrification in older urban neighborhoods. More human geographers have applied Giddens’s structuration theory.

Like other English-speaking social scientists, geographers and planners were probably more exposed to Giddens’s version owing to his prolific publishing in their language, critics’ equally rigorous publishing about him and his theory, and his

unique practice of answering his critics in print. Derek Gregory published an interview with Giddens that explored their mutual interests in understanding behavior in space and time. Giddens was innovative as a sociologist in incorporating spatial and time constraints from Torsten Hagerstrand's time-geography as theoretical structures.

Empirical Applications of Giddens's Structuration Theory

Giddens speculated that application of structuration theory would contribute new interpretations of a wide range of real-world behaviors. He himself only illustrated its application in reinterpretations of earlier research, as two more recent theorists refining his version, John Parker and Rob Stones, have also done. Searches of English language journals, chapters in books, and books found 59 empirical applications of structuration theory published between 1982 and 2008.

Geographers and planners' application of structuration theory has declined. Quite possibly, this decline may simply correspond with possibly temporary changes in the types of spatial behaviors of interest to geographers and planners. The decline may, however, also be due to more permanent reservations about the applicability of core structuration concepts, such as spatiality and duality of structure.

Types of Behaviors in Structuration Theory

Geographers and planners have applied structuration theory to a wide range of topics. For example, Jakub Novak and Ludek Sykora examined how a postcommunist city's spatial organization was being transformed by residents' reduced travel from their new suburban locations into its former core area. Manuel Aalbers inferred an acceleration in the physical and social decline of a neighborhood if disreputable loan sharks and slumlords moved in to cater to disadvantaged residents, including undocumented immigrants. Even so, geographers and planners' applications appear to have confirmed at least two hypothesized practical limitations of structuration theory. First, they have applied it more for interpreting the formal spatial behaviors of individual people and less those of groups or collectivities such as

nation-states and social movements, and they have not applied it to study either emotionally or culturally motivated or sanctioned behaviors. Second, the types of behaviors studied were observable formal social interactions, usually in modern rather than in traditional settings.

Reservations About Spatiality and Duality

Most geographers and planners have avoided engaging with theoretical and methodological reservations about structuration theory's core concept of the duality of structure. Only 3 of 25 applications measured the duality of structure in their analyses, and only 2 of these had a spatial duality of structure. The latter is where an area's geography created by human action becomes a structural enabler or constraint for future action. For example, Michael Dear and Adam Moos illustrated the latter for locations of licensed group homes, where a planned minimum distance between these homes ultimately reinforced clustering in the inner city.

Other researchers were constrained by their data from observing a virtual duality, and their applications confirmed a methodological reservation in the theory. This reservation is that ethnographic data through time or space for individuals are required for observing their instantiation of structural rules and resources, and these structures enable or constrain their or others' behaviors. Similarly, other researchers confirmed a theoretical reservation by measuring an agency-structure dualism, in which structure overpowered agency or vice versa. This reservation is that virtual structures may not apply to all spatial behaviors if the structural contexts for them endure in time and space even if they are not reconstituted by specific individuals in specific encounters.

Conclusion

At the height of structuration theory's popularity, many geographers and planners exploited it more for providing a conceptual framework and less for informing empirical analysis in their application. Moreover, few among others who applied structurationist concepts tested for the core concept of a (spatial) duality of structure. The possibly fewer future applications of structuration theory should therefore be mature ones, with geographers and

planners better appreciating when, and when not, to apply it to spatial behaviors of interest.

SUBALTERN STUDIES

Subaltern studies is a broadly influential academic movement whose goal is to refocus history on the unique role of subaltern or marginalized people in bringing about large-scale transformations in society. The implications of subaltern studies for geography are especially apparent in the group's exploration of spatialized categories of class, ancestry, and religion.

Subaltern studies began in 1982, when a collective of South Asian scholars in Britain, including Dipesh Chakrabarty and Partha Chatterjee, began publication of a book-length journal titled *Subaltern Studies*, edited by Ranajit Guha. Much of the collective's early work dealt with the politics of peasants who had been involved in the mass movements that ultimately led to India's independence. The journal's inauguration stemmed from a critique both of nationalist historians of India, who tended to focus on the local elites, and of orthodox Marxists, whose restriction of the concept of the working classes to industrial workers alone was, as the members of the subaltern studies collective argued, Eurocentric and badly suited to the varied economy of the Indian subcontinent.

Subaltern studies' turn away from traditional methods of historical research was signaled by ongoing debates over the definition of the term *subaltern*. Although influenced by the Marxist philosopher Antonio Gramsci, who used it to refer primarily to industrial laborers, in the work of the collective the word *subaltern* came to describe any group that is wholly left out of the elite. In this light, the collective's focus also developed in relation to long-standing populist debates in South Asia, from the nationalist writings of N. G. Ranga and L. Natarajan to the variegated Marxism of scholars like A. R. Desai.

Marxism and Subaltern Studies

In recent years, subaltern studies has often been seen as a post-Marxist movement because many of its scholars selectively combine Marxist theory with a variety of other influences. The relationships between cultural Marxism and subaltern studies were particularly close during the 1980s, with the group's focus on material analyses of

subaltern political movements. As such, subaltern studies theories developed in relation to transformations in British Marxism, wherein academics such as E. P. Thompson and Eric Wolf increasingly began to focus on ordinary people as the agents of history in Europe.

However, at that time, the rifts between subaltern studies and orthodox Marxism were also most apparent. Early-subaltern studies research placed particular emphasis on the self-contained autonomy of peasants, whereas some orthodox Marxists portrayed peasants as a byproduct of the particular history of capitalism in South Asia rather than a vibrant political group. Subaltern theorists also critiqued orthodox Marxist views on historical progress, including the assertion that every nation must pass through a transition from feudalism to capitalism. They argued instead that the histories of oppressed peoples needed to be recovered to produce a more accurate picture of major shifts.

Poststructuralism and Subaltern Studies

In the 1990s, the advent of poststructuralist theory was accompanied by a turn to discourse analysis that resonated with the collectives privileging of subaltern voices, voices that are often only minimally available in the historical record. As a result of this mutual influence, over time, subaltern studies research has focused increasingly on texts and textuality, including analyses of the ways elite leaders have defined subaltern groups. Some scholars have seen this move as evidence of greater theoretical sophistication inspired by the work of Jacques Derrida and Michel Foucault. Others, like the former subaltern studies collective member Sumit Sarkar, have seen it as a denial of human agency and therefore simply another form of subaltern disempowerment.

Critiques of Subaltern Studies

Partly due to its inception as a new school that was intentionally positioned between existing paradigms, subaltern studies has been the subject of ongoing debate. Some of the most influential critiques have come from Gayatri Spivak, who has long been associated with the collective. Spivak was one of the first to point out that not

only are fewer writings available by members of subaltern groups, but the conditions were also radically constrained in those instances when subalterns did speak.

Moreover, Spivak and others criticized subaltern studies for supposing that there could ever be a single authentic subaltern consciousness; this assumption originally led to a neglect of gender and other forms of diversity within subaltern groups. She further notes that the British colonizers were the first to consider subalterns as a particular class of subordinated people. As a result, attempts to give voice to the subaltern might only reinforce the unfair distinctions between subalterns and elites. Yet Spivak famously holds open the potential for further research provided that scholars recognize that the concept of the subaltern is simply a *strategic essentialism*, a type of necessary evil used to make practical advances.

Thus, subaltern studies faces four challenges. First, textual records contain few references to subaltern voices. Second, the references that do exist were often written by those in power. Third, even where their words were recorded, subalterns were often speaking in extremely imbalanced circumstances of the type they faced throughout their lives. Fourth, the division of people into elites and subalterns is itself the result of colonial oppression. Despite such obstacles, however, subaltern studies remains a vibrant movement whose scholars continue to use creative and alternative forms of knowledge to overcome the legacies of injustice.

SUBURBAN LAND USE

Because *suburban* is a relative—and highly subjective—term, suburban land use is best explained with respect to broader patterns of urban and regional development. The word itself carries both positive and negative connotations, depending on the specific context and/or frame of reference. On the one hand, suburbs are often thought of as a low-density alternative to the crowding, congestion, expense, and pollution of built-up urban centers. On the other hand, just as often, they are faulted for being exclusionary, inefficient, monotonous, and resource-intensive environments, and it is not uncommon for them to be described via the pejorative expression *suburban sprawl*. Suburban land use is without question lower in density and more spatially expansive than urban land use, but easy contrasts end there, as the two are increasingly just as complex in terms of the kind of activities they accommodate. This entry summarizes the history, character, and implications of suburban land use in the United States; variations on specific points apply worldwide.

The Three Waves of Suburbanization

Intraregional suburbanization, that is, the outward shift of development from high-density urban centers to low-density outlying areas, occurred via three distinct waves over the course

of the past century or so. The first wave, from the mid to late 1800s through the 1930s, gave rise to the so-called streetcar suburbs and was purely residential in nature. It resulted in a distinct pattern of land use—today called *transit-oriented development* and the cornerstone of the New Urbanism movement—wherein single-family homes were developed in a grid on small lots within easy walking distance of train stations or other public transport hubs.

The second wave, which began in the late 1940s and was both residential and commercial in nature, was fueled by the post–World War II housing boom and expansion of the interstate highway system. It produced an automobile-oriented pattern of land use, wherein homes were developed in various configurations on large lots far from attendant retail and service centers.

The third wave, which began in the 1960s and 1970s and was also both residential and commercial in nature, cemented a radical and more or less permanent transformation of regional structure from a monocentric to a polycentric pattern of spatial organization. Compared with earlier waves of suburbanization, which were essentially population shifts, it involved substantial employment shifts as well. For the first time ever, firms in all sectors of the economy, from manufacturing to high-order services, moved in mass to outlying areas, often clustering in entirely new “edge cities.” The resulting development was just as complex as in built-up urban areas but typically much lower in density and more spatially expansive. Today, most metropolitan areas exhibit a patchwork pattern of suburban land use made up of all three waves of decentralization.

From the Rust Belt to the Sunbelt

At the same time as these intraregional shifts were occurring, an equally important interregional shift also occurred. Specifically, the same personal preferences, advances in communications technology, and expansion of transport networks that led to intraregional suburbanization drew the population to less developed areas in the Sunbelt and elsewhere. Relatively small regions such as Atlanta, Georgia, now one of the nation’s 10 largest metropolitan areas, grew at an unprecedented rate after 1950 and, so, were developed

Figure 1 Spatial point patterns in the (A) New York City and (B) Atlanta regions

Source: Authors.

almost entirely in a suburban fashion. That is, they were built in a manner corresponding to the second and third waves of suburbanization and have only limited—or no—high-density urban development. This growth process can be thought of as interregional suburbanization, or the shift of development from older, built-up regions of the country in the Northeast to newer, low-density and automobile-oriented regions in the South and West.

The overall pattern of land use that these shifts produced is shown in Figure 1, which shows the New York City region on the top and the Atlanta region on the bottom. Both maps have the same scale and are identical in their dimensions—about 80 miles east to west and 60 miles north to south. The areas shown in the maps accommodate about 18.7 million and 4.7 million people, respectively. The points, shown in dark gray, are population-weighted centroids of census block group polygons (shown very faintly in the background), and the dark rays connect the points to the population-weighted center of their nearest metropolitan area division and to their nearest neighbor. The New York City region exhibits a very high-density urban core surrounded by suburbs and edge cities that become progressively less dense. The Atlanta region, meanwhile, has almost none of the high-density land use found in the New York City region and almost completely comprises low-density suburban land use. The contrast between the two maps is important because it illustrates not only how suburban land use differs from urban land use but also the relativity of the word *suburban*.

Conclusion

Finally, over the past 50 years, the desirability of suburban land use from a policy standpoint has been the subject of intense debate. At the core, suburbanization is driven by a combination of household preferences, rising incomes, and falling commuting costs—people demonstrably like living in low-density environments and can increasingly afford to do so, in terms of both the housing they purchase and the time they spend commuting. Suburbanization is also accelerated by certain market failures, though, including the failure of development to internalize the benefits of open space, the social costs of traffic congestion, and the cost of the services that it requires. Suburban

environments are also faulted for being exclusionary because they remain financially out of reach of large (poor) segments of the population and for being environmentally destructive and financially inefficient. Recently, suburbs have also been faulted on public health grounds for contributing to obesity because they do not facilitate walking, though this is a matter of some controversy. Environmental concerns cut both ways, because suburbs have simultaneously created a greater “land ethic” and led to the development of cleaner, more fuel-efficient technologies that have greatly reduced the impact of all forms of urbanization, including suburbanization. Going forward, it seems likely that the debate over suburban land use will increasingly turn on whether or not it continues to appeal to household preferences and, more generally, the extent to which it supports the interests of society at large.

SUBURBS AND SUBURBANIZATION

In the sense of the ancient Roman term *suburbium*, which referred to areas outside the city but within a convenient daily traveling distance from it, suburbs have existed as long as there have been cities. *Suburbs* are still commonly defined as the area within commuting distance of a central city, but now they often include more than half the population and jobs of metropolitan areas, and many residents of suburbs no longer commute to or even go to the central city.

Since the 19th century, suburbs have grown to become one of the central facts of modern urban civilization. Processes of suburbanization not only have led to a vast increase in urban area and major changes in transportation and urban form but also have prompted intense and ongoing debates over ideas of good living environments, the appropriate physical setting for a community, the regulation of urban development, and the goals and scope of urban and regional governance. Suburbanization thus involves multiple

processes of population growth and urbanization, technological change in transportation, the transformation of urban form, and dynamic conflicts over ideas of the good city and how to manage urban growth to attain it. Although decentralization and a shift toward automobile-based transport have occurred everywhere, suburbanization processes have produced rather varied outcomes in different places, depending on the timing, economic structure, land ownership patterns, and governance institutions.

Major Stages of Suburbanization

It is possible to identify four broad stages of suburbanization, led by the United States, but with later parallels in the other developed countries. The first stage occurred in the mid 19th century, when new passenger train services allowed the creation of residential suburbs for the wealthy, who could afford daily rail travel to the high-density, compact central city. These early railway suburbs were often beautifully designed experiments in gracious countryside living, in exclusive planned residential estates such as Llewellyn Park in New Jersey, the Main Line communities outside Philadelphia, or Riverside outside Chicago. Described as “bourgeois utopias” by Robert Fishman, these were successful in generating a model of low-density, purely residential suburbs as the ideal in family housing and presented a stark contrast to the gritty and polluted industrial cities of the day. The vast majority of jobs, shops, and housing continued to be located in mixed-use areas in city centers.

Second is the period from the 1860s to the 1930s, when the introduction and rapid spread of horse-drawn trams and then electric streetcars allowed an accelerating expansion of suburban development for the middle and upper classes, creating what are now known as *streetcar suburbs*. Since the area from which inexpensive daily travel to central-city employment and retail areas expanded exponentially, suburban land was cheap, and single-family detached housing became affordable to a much larger share of the population. The house-building industry expanded and began to create a more differentiated range of products for different classes, from self-built prefabricated kits for the lower middle class to the

Suburban sprawl, Las Vegas, Clark County, Nevada

Source: Lynn Betts, U.S. Department of Agriculture, Natural Resources Conservation Service.

rather substantial dwellings for the upper middle class. Some daily retail uses located in strips along major streets carrying streetcar tracks, with residential areas of detached houses on grids of streets up to about a 10-minute walk from the streetcar lines. Most retail and employment remained in the center, except for the growing numbers of suburban factories along the railway lines leading out of the city.

The third period began after World War II, when increasing car ownership, expansion of arterial roads and limited-access highways, and the new availability of government-guaranteed mortgages generated a large-scale house-building industry that built single-family detached homes for all classes, creating vast areas of purely residential development, a trend reinforced by the increasing use of zoning to prevent mixing of

land use. Although some developers attempted to build complete communities, with town centers, parks, and schools, most developments contained only housing and streets to access them and little else. Shopping centers were built in the suburbs from the mid 1950s onward, as retailers followed their customers out of town, but central cities continued as major employment and retail concentrations.

Fourth, since the 1960s, as both factory and then office jobs relocated to suburban and exurban locations, suburbs surpassed central cities in both population and jobs and became increasingly independent of the old central cities. By the mid 1960s, more than half of the population of the United States lived in suburbs. The process of outward expansion accelerated, as job decentralization to what Joel Garreau famously

labeled *edge cities*—large clusters of office, manufacturing, and retail jobs at exurban highway interchanges, frequently associated with airports—allowed a much larger commuting range for their workers. From the 1970s on, many U.S. central cities began a precipitous decline, as those who could afford to leave fled, leaving the poor and the racialized minorities in shrinking and often crumbling core areas with few job prospects and declining schools and services. During the 1990s and later, many central-city areas such as Manhattan and Portland saw population increases, with recolonization by the affluent and gentrification of selected central areas, but the dominant trend has continued to be dispersion of both jobs and population to locations ever more distant from the original centers, giving rise to exurbia and what Robert Lang has called *edgeless cities*.

These patterns were more characteristic of the United States than elsewhere, in part because of earlier and higher rates of automobile ownership and expressway building, large government subsidies for home ownership, and strong property rights that made planning restrictions difficult, and in part as a reflection of differing preferences. For example, in France, the central cities remained the most desirable housing locations for the affluent, and racial minorities found themselves pushed to the suburbs. Even so, in France, issues of urban sprawl became increasingly identified as a policy issue since the 1990s. In most Northern European countries and in Canada, processes of land development were much more tightly regulated, and the kinds of edgeless cities seen in the United States are virtually unknown, as even with increasing automobile use and considerable lower-density development, most development was contiguous with existing urban areas and at higher densities. In Spain, cities such as Barcelona and Madrid revitalized and intensified their central areas and built suburbs at extremely high densities, linked to the expansion of heavy-rail public transit.

In Japan, excellent public transit systems and limited road space and parking in central areas combined to produce highly distinctive suburban development patterns, with much greater reliance on public transit, particularly in metropolitan areas. More significantly, highly fragmented land

ownership, tiny farms, and weak regulation of land development contributed to extensive patterns of metropolitan region growth over huge areas, with plot-by-plot development, highly mixed land uses, much remnant agricultural land, and routine shortages of public infrastructure such as sewers, roads, and parks. Such patterns of suburbanization demonstrate many of the characteristics of the “extended metropolitan regions” identified by T. G. McGee and Ira M. Robinson. In other Asian countries, the high-density, pre-urbanization populations and highly fragmented land ownership were characteristic of wet-paddy rice agriculture. This combined with increasing mobility and urbanization to produce suburban areas with a mix of rural and urban land use and a mix of formal and informal development, with factories and fields incorporating vast areas into growing urban economies. Modes of travel including bicycles and two-stroke motorbikes shifted, with increasing affluence, to automobiles and trucks.

The other major form of suburban development in many developing countries has been large-scale, planned “new towns” and office parks on the urban fringe, often near airports and expressways, often in the form of gated, exclusive developments for the wealthy and for expatriates from developed countries. Gated communities were seen initially in the United States but are now also increasingly seen in developing countries. Although these are diverse, usually they are upscale developments entirely outside municipal jurisdiction. They provide all their own services, often including gates and security guards and sometimes golf courses and other leisure facilities. Instead of paying property taxes to a municipality, residents pay fees to a homeowners’ association or management agency that maintains the shared facilities.

Changing Ideas of the Good City

Worsening environmental conditions in 19th-century industrial cities not only pushed many people out of the city (if they could afford the longer commutes) but also contributed to the birth of powerful and enduring conceptions of the nature of the city as dreadful and corrupting. Similarly, suburbs began to be perceived as its bucolic antidote in the countryside. As the sanitary reform

and city-planning movements gained traction with devastating exposes of the degrading and corrupting slum conditions during the final decades of the 19th century, the idea of the residential suburb as bower of family life was reinforced. The ideal of living in the countryside but with access to the city was firmly established by the early 20th century, just as the countryside began to recede farther away with the accelerating spread of streetcar suburbs.

This analysis of urban pathology was reinforced by the work of the Chicago School of sociology, led by Robert Park and Ernest Burgess, which equated big-city life with the loss of the moral order of the traditional rural community, rising vice and crime rates, and increasing anomie. These ideas were later widely criticized for their environmental determinism—the idea that physical environments rather than social conditions determine culture—but were nonetheless hugely influential. For many, the obvious solution was dispersion of population and the emptying out of the city, arguments that provided powerful ideological support for suburbanization. Such antiurban ideas became dominant, especially in Britain, the United States, Canada, and Australia, and the idea of the detached single-family home in residential-only areas became the prevailing image of a good residential environment.

As mass suburbanization emerged in the 1950s as the dominant pattern, and the newly accessible suburban home ownership was enthusiastically embraced by the working and middle classes, a new, more critical interpretation of suburbanization grew prominent. Critics and social theorists began to identify a new set of social pathologies that they associated with the new suburbs, including isolation, the sorting out of classes into segregated areas, mass conformity and loss of individual identity, and a substitution of consumerism for community. This view of suburbanization as a destructive and failed social experiment was perhaps never better put than by Lewis Mumford in his monumental work *The City in History*:

In the mass movement into suburban areas, a new kind of community was produced, which caricatured both the historic city and the archetypal suburban refuge: a multitude of uniform,

unidentifiable houses, lined up inflexibly, at uniform distances, on uniform roads, in a treeless communal waste, inhabited by people of the same class, the same income, the same age group, witnessing the same television performances, eating the same tasteless pre-fabricated foods, from the same freezers, conforming in every outward and inward respect to a common mold, manufactured in the central metropolis. Thus the ultimate effect of the suburban escape in our time is, ironically, a low-grade uniform environment from which escape is impossible. (p. 486)

In the 1970s, these early indictments were deepened by the work of humanistic geographers, who argued that much of the contemporary suburban landscape was so repetitive that it inspired little sense of place in its residents, or anyone else, and epitomized placelessness. These critiques were amplified by arguments by feminist geographers that suburbs served to trap women in narrow reproductive roles, in places where the physical design served to isolate women from access to paid employment and services. Marxist geographers saw the development of suburbs primarily as a strategy for the deployment of surplus capital, in efforts to stave off an accumulation crisis. Social geographers saw the growing racial divide—between affluent, largely white suburbs, with excellent services, and poor, declining central cities, which were increasingly populated by visible minorities—as a powerful expression of systemic racism. Not everyone agreed, however, with other observers quick to defend the new suburbs as an opportunity for better housing for many and just as likely to generate meaningful places and communities as other urban patterns.

Suburbanization as a Contested Process

Inherent in the process of suburbanization has been a continuously shifting relationship between municipal boundaries and areas of new land development. While early in the 20th century, it was routine for U.S. cities to annex new growth areas by expanding municipal boundaries, in many places, that became much more difficult, usually because adjacent municipalities resisted amalgamation with a central city. The failure to grow urban boundaries to encompass newly

developing suburbs, however, had decisive consequences. First, growth often occurred most rapidly in places with less robust city planning and administrative and fiscal capacity. In the United States, suburbanization produced major conflicts, in the 1970s, between developers and the communities where they were building, over environmental impacts, congestion, and the high costs of suburban growth to existing taxpayers. Some of this was due to the self-interest of those who had found their suburban escape and wanted to slam the door behind them, but it was also a pragmatic response to serious problems of rapid growth and infrastructure shortfalls. This led to growth management efforts by municipalities that sought greater regulatory control over the speed, location, and form of any development and to a large urban politics literature on the political power of progrowth actors in municipal politics. Significant successes in managing growth were few and hard-won, and since 2000, property-rights advocates in several states have successfully challenged growth management approaches as unacceptable restrictions on land ownership (e.g., in Oregon, where long-standing urban growth boundaries were successfully challenged in a referendum in 2006).

Second, metropolitan regions in the United States now show high levels of political fragmentation, with multiple independent municipal governments of various sizes responsible for their own planning, schools, and infrastructure, making larger-scale regional coordination difficult and exacerbating social inequities. Poor and minority populations are concentrated in inner cities, with declining tax bases and substandard schools and services, while the middle-class areas in the suburbs often have excellent services and strong tax bases. Such divisions have also raised concerns about the spatial mismatch between the locations of jobs and housing, as most new jobs at all income levels are located in the suburbs but many workers cannot afford the housing in those suburbs. Fragmentation also positively encourages small municipalities to exclude unwanted land uses such as affordable housing or garbage dumps, leading many to argue that fragmentation has been a major factor behind residential segregation and exclusion and has contributed to the high levels of social polarization in American

metropolitan areas. Such suburban governance problems have prompted repeated attempts to create metropolitan and regional governance structures, which have so far largely failed, apart from Portland, Oregon, and Minneapolis–St. Paul. Other countries such as Canada, Australia, Japan, and Sweden, have been much more active in attempting metropolitan governance schemes for whole urban regions, using tax redistribution to ensure that schools and services are relatively consistent between suburbs and central cities and avoiding the extraordinary collapse of so many central cities seen in the United States.

Since the 1990s, the understanding of suburbanization has again been transformed, as the argument that there are serious dysfunctions associated with low-density suburbanization—commonly labeled “urban sprawl”—on a mass scale became more widely understood. The basic argument was that while it may be possible for a small portion of metropolitan populations to live at very low densities, when the majority do so and when most travel is by private car, then even with massive investments in roads, the resulting traffic creates endemic problems of congestion, pollution, and energy consumption. Low-density, automobile-dependent suburbs are increasingly attacked as the primary obstacle to greater urban environmental sustainability. These accusations have been combined with the ideas of the New Urbanists and of smart-growth advocates in support of stronger attempts to create more compact, mixed, and walkable suburban development forms. These arguments have been influential, particularly among municipal governments that have struggled with the costs of managing extensive development patterns, but suburban and exurban housing has continued to be popular among home buyers, so most attempts at managing growth in the United States have had limited success.

These debates do, however, once again underline the ongoing reality of suburbanization as a dynamic and fundamentally contested process at the intersection of conflicting ideas of desirable residential environments, environmental sustainability, land ownership and property rights, urban governance and citizenship, and social equity.

SUI, DANIEL (1965–)

One of contemporary geography's leading theoreticians of geographic information science (GIScience), among other topics, Daniel Z. Sui has played an important role in shaping the trajectory of the discipline.

After completing bachelor's and master's degrees in science at Peking University and earning a PhD from the University of Georgia in 1993, Sui taught for 16 years at Texas A&M University, where he held the Reta Haynes Endowed Chair in Geography as well as serving as assistant vice president for research and director of geospatial information science and technology (2004–2008). In 2009, he moved to the Ohio State University as Distinguished Professor of Social and Behavioral Sciences and director of the Center for Urban and Regional Analysis. He was a recipient of a 2009 Guggenheim fellowship. He has also held a variety of visiting fellowships and professorships. Starting in 2007, he served as editor-in-chief of *GeoJournal* and as a regular columnist for *GeoWorld*. His career has also been notable for his extensive publication record, including several books and monographs and countless journal articles, and for millions of dollars in external grant funding. He has also mentored numerous graduate students.

Sui's corpus of work lies largely in the domain of geographic information systems (GIS) theory and applications. His works address, for example, an exceptionally wide array of topics, including neogeography and the "wikification" of GIS, volunteered geographical information, digital cities, location-based services, small-world networks, fuzzy logic, neural networks, fractals, the use of geospatial technologies for surveillance (including geoslavery), the environmental impacts of digital technologies, ecological inference, and empirical applications of GIS to topics as diverse as homeland security, medical geography, binge drinking, traffic accidents, transportation modeling, natural disasters, food insecurity, property value appraisal, water management, floodplain mapping, urban obesity, landscape fragmentation, mental maps, urban modeling, urban heat islands, urban sprawl in Asia and the United States, voter turnout, Internet-based and GIS education, and Tobler's First Law. A consistent

theme throughout these works is the social uses and consequences of digital geospatial technologies, with a critical eye toward the costs as well as the benefits. Sui has also been instrumental in fostering a rapprochement between the GIS and critical human geography communities since the 1990s, when a productive and mutually transformative dialogue began to replace mutual recrimination. His work has become increasingly epistemologically self-conscious, and he helped pioneer the use of poststructuralist concerns such as the social origins and consequences of representations in the GIS literature.

analysis has its roots in the applications of hand-drawn, sieve-mapping overlay techniques used by landscape architects in the late 19th and early 20th centuries. In the 1960s, I. L. McHarg and others refined and advanced the overlay techniques by proposing a procedure that involved mapping data on the natural and human-made attributes of the environment and then presenting this information on individual, transparent maps using light to dark shading (low suitability to high suitability). When the maps were overlaid, the darkest areas then showed the most suitable parcels of land for particular types of land use.

Land suitability methods can be applied for tackling site selection problems or in the context of comprehensive planning. The aim of the site selection analysis is to identify the best site for a specific activity, such as a shopping center, an industrial plant, or a public school, given the set of potential or feasible locations (parcels of land). The problem is to rank or rate alternative sites based on their characteristics so that the best location can be identified. The comprehensive planning aims at identifying the best spatial pattern of land uses such as residential, industrial, commercial, and recreational. The procedure involves developing suitability maps for each land use based on criteria considered as important for the specific activity. The suitability maps are then overlaid to identify areas suitable for more than one land use.

The hand-drawn mapping technique for suitability analysis has been widely recognized as a precursor to the classical overlay procedures in geographic information systems (GIS). There are two fundamental classes of map combination (overlay) operations in GIS: Boolean overlay and weighted linear combination (WLC). Given a set of suitability maps and corresponding threshold values, the Boolean AND operation results in classifying areas as suitable for a particular land use if each suitability map meets its threshold. Conversely, the Boolean OR operation identifies suitable areas as those that meet at least one suitability threshold value. The WLC approach involves standardization of the suitability maps, assigning the weights of relative importance to the suitability maps, and then combining the weights and standardized suitability maps to obtain an overall suitability score. The classical GIS approaches to

SUITABILITY ANALYSIS

Suitability analysis is concerned with determining the most appropriate spatial pattern for future land uses according to specific requirements, preferences, or predictors of some activity. The

suitability analysis have recently been advanced by integrating GIS with multicriteria decision analysis methods.

SUNBELT

The Sunbelt is an innately geographical idea but one without a clear geographical definition. The term connotes a region (or regions) of the United States characterized by rapid post–World War II economic maturation and growth. In economic terms, two trends stand out. The first of these is the relocation of U.S. manufacturing employment from the Great Lakes region (“Rust Belt” or “Snowbelt”) to new industrial clusters in the warmer climates of the southeastern and

southwestern United States. This shift was fueled in part by the comparative advantages of lower labor costs and proximity to raw materials (especially oil), as well as by the advent of air conditioning, which made tolerable the extreme heat and humidity that characterized much of the southern tier of the United States. The second, more recent, trend is the spectacular growth in producer services jobs in banking, insurance, information, and technology in the urban Sunbelt (metropolitan regions such as Charlotte, Atlanta, Austin, Phoenix, and San Diego; see Figure 1).

The “belt” in *Sunbelt* refers to a southern, balmy arc of the United States, stretching from the Carolinas to California. The origins of the term are commonly attributed to Kevin Phillips in his book *The Emerging Republican Majority*. Phillips argued that the Sunbelt region had evolved into a key geographical focal point for a conservative revolution in American politics, characterized by an unlikely coalition of disaffected Southern whites, Western libertarians, and California cold warriors. This thesis has been complicated by subsequent elections, most notably the 2008 U.S. presidential election, which highlighted how problematic it is to group together states such as Georgia, Florida, California, and Arizona politically.

Population growth in the contemporary Sunbelt has partly resulted from in-migration from northern, particularly Rustbelt, states. A large proportion of these in-migrants are retirees, although the demographic makeup of these new arrivals is by no means homogeneous. Furthermore, the southward shift in manufacturing and service jobs growth has been mirrored by a shift in major immigrant destinations from the traditional immigrant gateways of the major northern cities to places in the Sunbelt. Many of these “New Americans” have adopted the auto-centered, suburban lifestyle that is predominant in the Sunbelt, resulting in remarkably diverse and decentralized immigrant communities in some Sunbelt metropolitan areas. Places such as Chamblee, Doraville, and Norcross in the suburbs of Atlanta and places such as Irving, Garland, and Plano in the Dallas metropolitan area have attracted large non-native-born populations in largely suburban settings. Some observers

Figure 1 Although its definitions and meanings are often nebulous, the Sunbelt (designated in blue) is generally taken to mean the balmy, southern reaches of the United States.

Source: Barney Warf.

have argued that the essential qualities of a Sunbelt metropolis are that it is young, fast growing, auto centered, and sprawling, but the Sunbelt is also increasingly home to diverse groups of new immigrants.

Is all this enough to make the Sunbelt a coherent region? Attempts at defining the Sunbelt as a coherent geographical region fall short in several respects. First, it is not monolithic. The stereotypical image of the sun-drenched southern tier of the United States transforming from an economic backwater to a large swathe of nouveau riche fails to capture the spatial variability within the Sunbelt. First, much of the Sunbelt continues to struggle with the challenges presented by the pronounced urban-rural split in terms of spatial wealth distribution. Second, the term is relatively imprecise and geographically uncertain. Does

Bend, Oregon, which lies in the high desert region in the rain shadow of the Cascades and has experienced explosive amenity-fueled growth qualify as part of the Sunbelt? What about other Sunbelt regions outside the United States, such as Australia's Gold Coast and England's M-4 corridor? Third, some have argued that the Sunbelt terminology was a construct that had been thrust on those living there. One of the most notable observers of American vernacular regions, Wilbur Zelinsky, noted as much when he wrote in a seminal article that *Sunbelt* was a "deplorable" term, because it was created by elites and handed down to the people rather than the other way around.

Although the term *Sunbelt* is commonly used in both scholarly journals and the popular media and is widely accepted as a regional moniker, it is

less clear where the region begins and ends or what constitutes its key elements. Like other “belts”—Gun Belt, Bible Belt, and Grain Belt—there is something there, but it is difficult to say what or where.

Corey M. Johnson and Keith G. Debbage

multispectral images) of the known training data are calculated for each class and then used for inputs to the classification algorithm for evaluating and assigning the rest of the data to classes.

Various classification algorithms (or classifiers) may be used in supervised classification to assign a data value to a class. These algorithms can be categorized into parametric and nonparametric approaches. The choice of a particular algorithm depends on the nature of the input data. Parametric classification algorithms assume a normal (or Gaussian) distribution of observed parameters in the training data, while nonparametric algorithms make no such assumption. The most widely used parametric classification algorithm is the maximum likelihood algorithm, in which data are assigned to the class having the highest probability (or likelihood), and the several commonly used nonparametric algorithms include parallelepiped, minimum distance, and neural network-based algorithms.

The quality and quantity of training samples can affect the output of supervised classification. Ideally, each training site should be independent of the others by selecting it through random sampling. However, this is often not possible due to cost and accessibility issues. Training polygons or seeds through automatic growing is often used in the selection of training data to save time and cost. Supervised classification depends heavily on the cognition and skills of the training analyst.

DongMei Chen

See also **Data Classification Schemes; Unsupervised Classification**

SUPERVISED CLASSIFICATION

Supervised classification is the process of automatically grouping data into a set of classes by setting up prototypes using a priori knowledge obtained through training. It often involves selection of training data that can represent homogeneous examples of each class. There are a number of ways to collect training data, including on-site fieldwork, manual interpolation, automatic seeding, and personal experience. The parameters (typically, mean vector and covariance matrix in

SUPRANATIONAL INTEGRATION

Supranational integration can be described as a process in which two or more nation-states or subnational regions within states come together by themselves or are brought together by a third party to form a new territorial configuration. As a concept, it usually refers to state-level memberships of political coalitions, but it can also be boosted by subnational organizations such as regional councils.

Supranational integration has been a globally important feature of political and economic life, especially since the end of World War II. It has been regarded as important for reducing political tensions and disparities between both nation-states and subnational regions. Apart from its political and economic origins, supranational integration has sometimes taken on a distinctively cultural character. This is the case when regional identity and a shared cultural history, for example, serve to bind administratively separate regions together and trigger the integration process. It can be claimed, however, that the emphasis more recently has been on economic issues, as much supranational integration takes place to increase competitiveness and to better performance in interregional competition. Supranational integration has thus been to a large extent linked with the interconnection and globalization of the world economy, where, among other things, new cross-border regional entities are being established with a view to better economic performance. The boosting of the economy is efficiently supported in this context by a diminishing of the role of borders, which are often regarded as obstacles to growth. Stability, on the other hand, is gained by reducing the regional cross-border imbalances and tensions caused by differences in political and economic structures and thereby evening out development.

The common goals laid down in the process of supranational integration serve to some extent to reduce the sovereignty of the individual state in favor of collective interests, given that both nation-states and subnational actors usually enter into agreements that enhance supranational cooperation by establishing joint institutions that are subject to sets of common rules. Supranational integration has traditionally focused on removal

of barriers to trade and promotion of the free movement of labor, capital, and goods.

As a consequence of the partial transfer of sovereignty to supranational bodies, supranational integration is considered to “hollow out” the nation-state. There has recently been some debate, however, as to whether the state is a passive reactor to these processes or proactive, as devolution of power can equally well be a strategic choice made by the central authorities. Also, only a certain amount of sovereignty is normally given to multinational bodies in connection with supranational integration, as the integration processes are usually controlled by nation-states. If all the sovereignty is given (or taken) away, the process becomes a merger rather than an instance of integration.

The rescaling of nation-states has nevertheless been a part of a broader pattern of regionalist thinking in which devolution of power is regarded as an essential element. Power is, however, said to be delegated not only upward to supranational institutions or downward to regions and cities but also outward to various nonstate bodies such as nongovernmental organizations and businesses. Rescaling has thus led to two-level or even three-level structures in which subnational and regional organizations and institutions implement supranational integration strategies at the practical level (often together with various development agencies and enterprises), but nation-states—and, increasingly, multinational bodies—nevertheless wield the decisive political and administrative power.

As a result of reterritorialization of the state and rescaling of its governance, supranational integration has resulted in the emergence of a number of recently conceived cross-border regional entities. These “nonstandard regions” are constantly being institutionalized by region builders all around the world. Especially in Europe, the idea of “a Europe of the regions” has led to the formation of new cross-border regions. Some of them are truly functional, but in some cases, it is the borders of the nation-states that remain as the lines of division, and no genuine cooperation or uniform supranational regional identity has actually evolved.

All in all, cross-border arrangements, that is, the coalitions and treaties that nation-states, subnational regions, and, to some extent, supranational bodies make to gain economic advantages and improve their stability, are essential for

supranational integration. In supranational integration, politics and business are immanent and usually intertwined to form sometimes fuzzy networks of governance in which several administrative levels are involved. Supranational integration can be either multilateral or bilateral in nature, but the essential point is that it should encompass international decision making and as such enable national boundaries to become more porous.

Supranational Integration as a Process

Supranational integration can also be conceptualized as a process that involves numerous starting points and stages. On the general level, the process of integration contains elements from below and from above, making it characteristically either a top-down or a bottom-up process by nature or something in between. *Functioning from below* means simply that the subnational authorities do not wait for formal procedures from above before initiating cross-border cooperation but use new types of interaction without justification from the formal administration, while *functioning from above* refers to forms of development in which regions are established and are given power and freedom of action by the formal authorities and central governments (nation-states) or by multinational organizations. Supranational integration can evidently take on quite different shapes and paths and aim at quite different things. Sometimes, region building can be quite explicit, as in the case of new competitive regions or “growth corridors,” but occasionally, the construction process is more vague, veiled, and contested. Such is the case when integration takes place against the will of the dominant political forces, being imposed by nongovernmental organizations and private actors, for example.

Although supranational integration is not necessarily anything more than a bilateral cooperation agreement in a defined sector concluded between states or cross-border regions, it is common for the integration process to have several ingredients and aspects. Supranational integration, especially when taking place between subnational regions, is typically a region-building process in which a new region is institutionalized and identified as a distinct unit in the spatial structure of society. There are several mechanisms by

which this can happen, but one key aspect is the increasing of territorial awareness by the creation of regional symbols, including the name of the region. More essential in the case of newly established supranational regions, however, is the emergence of region-based institutions. These exist to a large extent due to the establishment of the region itself, but at the same time they produce and reproduce the region, for example, by constructing regional symbols and representing the borders of the region. Regional development agencies and regional councils that operate at a supranational level are examples of such region-based institutions. As region building is about the discursive production of a region, these actors are also builders of regional identity. This is essential, as a certain amount of regional identity is thought necessary to bind inhabitants to their region and create a regional spirit of initiative. The process of supranational region building is in a sense twofold, however, as, on the one hand, regions are represented as fixed, bounded entities but, on the other hand, they are also networked, porous, and fluid. New regions are thus engaged in competition; but they also, according to the ideas of the new regionalism, which emphasize the significance of linked city-regions, collaborate within various supranational networks and assemblages. New supranational configurations, often created to promote competitiveness, are in direct competition not only with each other but also with administrative regions that have much longer histories.

Cases

An abundance of cases of supranational integration exist, including the regions defined by the North American Free Trade Agreement (NAFTA), the southern Latin American common market (Mercosur), and the Association of Southeast Asian Nations (ASEAN). Perhaps the best-known and most developed case, however, is the European Union (EU), where the shared principles of cohesion and a single market have paved the way for supranational integration covering almost the whole of Europe. European integration has been regarded as an interstate process implemented mainly by central governments. The main bodies that run the EU and approve its legislation include the Council of the European Union, the European

Figure 1 The Barents Euro-Arctic region
Source: Courtesy of the Arctic Centre, University of Lapland.

Commission, and the European Parliament. The aim of this integration has been quite typical of contemporary supranational integration processes in general, that is, to develop freedom and to promote economic and social progress. Although the EU was officially established in 1993, when the Maastricht Treaty was approved by the 12 founding members, its history may be traced back to the 1950s, when the European Coal and Steel Community was established. This developed into the European Economic Community in 1957, with the signing of the Treaty of Rome. The EU currently has 27 member states, which have agreed to maintain and strengthen peace, prosperity, and freedom at a supranational level.

The single market in Europe, with its increasingly porous borders, has also paved the way for supranational regions within the EU, resulting in smaller-scale supranational integration. Good examples of this are the Euroregions, of which there are about 70 at the moment, mostly concentrating on cross-border cooperation in the fields of culture, tourism, and other economic activities. The political power of the Euroregions is limited, however, as they are mostly run by regional and local authorities. Some of the Euroregion initiatives have their roots in the 1950s, but most of them were created in the 1990s, for example, the Cross-Channel and Baltic Euroregions. As inter-regional (and, from the EU's standpoint, intercontinental) competition is considered more or less unavoidable, the institutionalization of internationally competitive supranational regions inside the EU is currently attracting increased support.

Another example of supranational integration, at both the state and the regional level involved, is the establishment of the Barents Euro-Arctic region (BEAR) in the far north of Europe (Figure 1). The official act of establishment took place in Kirkenes, Norway, on January 11, 1993, together with the founding of the intergovernmental Barents Euro-Arctic Council (BEAC) and the interregional Barents Regional Council (BRC). The initiative to establish the region (also known as Barents Cooperation) was actually taken by the Norwegians, and it represented a political strategy for handling the opportunities and also the problems related to the post-Cold War reality of East-West relationships. The original proposal was made by the Norwegian Ministry of Foreign Affairs, and as such, it

is often described as an attempt to widen and restructure ongoing activities in order to promote security. At the moment, the Barents Region includes the 13 subnational territories located in Norway, Sweden, Finland, and Russia that are members of the BRC. Economic issues concerned with energy, natural resources, and business cooperation have been high on the agenda recently, but several projects dealing with security, health, culture, and education have also been implemented by multilateral consortia.

SURFACE WATER

Surface water is intrinsic to global, dynamic human activities: population and urban geography, politics, economics, and culture. As global climate change begins to influence the geography of surface water, the world's population must adapt in concert. Surface water is discussed here as a factor shaping the physical and cultural landscape, which includes the geography of surface water, the different surface water types, its effects on the physical environment, and its importance to the activities of humans.

Approximately 70% of the Earth's surface is water. Surface water is an important part of the hydrologic cycle and is defined as water above the surface that collects in oceans, seas, rivers, streams, lakes, ponds, springs, wetlands, and glaciers. Water found in the atmosphere or contained in rock beneath the surface (groundwater) is part of the hydrosphere but is not categorized as surface water. Because the Earth is a closed system, the total amount of water is constant. However, water is always on the move and is a renewable resource constantly recycled through evaporation, condensation, and precipitation. Through these processes, and over geologic time, surface water will change phase and geography repeatedly to become groundwater, atmospheric water, terrestrial water, and oceanic water. Although not addressed here, it is important to mention the interconnectedness of surface water and groundwater; for instance, some water bodies such as springs and seeps are the visual expression of groundwater at the surface.

The Geography of Surface Water

The majority of surface water is found in the oceans (97.2%) and is saline. Oceans are the largest input to the global hydrologic cycle, where 320,000 cubic kilometers evaporates from their surfaces each year. The world's oceans are highly influential on climate patterns, as these massive water bodies act as a sink for solar energy. Oceanic water circulation moves warm water away from the equator, while cold water is forced toward lower latitudes. These massive transfers of energy drive global temperature and precipitation patterns and explain a great deal about climate and biogeography. For example, the cold current flowing adjacent to the western edge of South America produces dry air and is a factor in the formation of the Atacama Desert climate, while the warm current of the western Atlantic Ocean flows toward Western Europe and keeps annual temperatures mild.

The remaining 2.8% of the Earth's hydrosphere is the nonocean component, and only a tiny 2.5% of this water is fresh. Termed the *cryosphere*, ice sheets and glaciers constitute the frozen fraction of the hydrosphere and are the largest nonocean component of surface water (2.15% of the total hydrosphere). These huge volumes of ice are

concentrated in alpine regions on every continent and at the polar latitudes, specifically the Arctic, the Greenland Ice Sheet, and the continent of Antarctica. Only a fraction of the total global hydrosphere is fresh, liquid surface water: Lakes and reservoirs make up 0.009%, while only 0.0001% is found in rivers and stream channels. The remaining surface water is found in inland seas and saline lakes (0.008%) and in soil moisture (0.005%).

Drainage Basins

The expression of surface water on the landscape is largely controlled by geology and topography. When water flows downhill to collect in a water body, the land surface area that contributes to that collection is termed a *drainage*, or *catchment*, basin. Drainage divides separate drainage basins, where the division of two basins occurs because of higher ground at their shared perimeter. These divisions can be distinct ridges or subtle rises in elevation. A drainage divide may also be called a *watershed*. However, in some cases, *watershed* may also refer to the drainage basin itself. As a classic example of scale in geography, drainage basins can be subdivided into progressively smaller units.

Types of Surface Water

Runoff

Running water is the most important geomorphic factor on Earth. Surface water in the form of runoff is generated when a precipitation event saturates the soil and subsurface to such a degree that it can no longer absorb the moisture and water begins to flow across the land. The volume of runoff is determined by several factors, including the local climate, volume of water generated by the precipitation event, duration of the event, land slope, soil type, geology, and vegetation. Surface runoff can degrade the landscape if the velocity of water is great enough to entrain sediment and erode the soil. Snowmelt runoff is an important contributor to the volume of water in streams and rivers, especially in mountainous regions around the globe.

Streams and Rivers

When surface water flows across the landscape and is concentrated, a stream forms. Streams and

rivers carry surface water and sediments downstream toward a local (lake) or ultimate (ocean) base level. Rivers transport, deposit, and store extensive volumes of sediment that create landforms in fluvial and coastal plain environments, and they are the primary factor involved in terrestrial landscape formation. Over geologic time, surface water deposits materials that form sedimentary rocks. Globally, the longest river is the Nile, while the largest river (in total volume) is the Amazon. Because of the widespread influence of humans, most rivers have been modified in some way.

Lake and Ponds

Lakes are large terrestrial bodies of water that occur where water collects in a depression or basin, and they may or may not have an outlet. Ponds are smaller water bodies than lakes, although debate remains about the definition of each, specifically pertaining to the threshold where a pond is large enough to be deemed a lake. Many sources cite lakes as water bodies large enough to generate waves across their surface. Most lakes on Earth are found in the Northern Hemisphere, where hundreds of thousands of depressions litter the landscape as a result of Pleistocene continental glaciation and are now water filled. The largest lake in the world (in surface area) is the Caspian Sea, while the deepest is Siberia's Lake Baikal (also the largest in volume). Although it is called a sea, the Caspian is a saline lake that lacks a drainage outlet.

Oceans and Seas

The oceans of the world are divided into four main water bodies: Atlantic, Pacific, Indian, and Arctic. There are no distinct geographic divisions defining where one ocean begins and another ends. Seas are smaller, saline water bodies geographically joined with oceans and also lacking definitive boundaries. The nomenclature for seas is not consistent throughout the globe; however, some gulfs are seas, such as the Persian Gulf, while some seas are saline lakes, such as the Caspian Sea, as mentioned above. The International Hydrographic Organization is the agency responsible for classifying the world's water bodies, and this agency should be referenced for specific naming conventions for global water bodies.

Surface Water and Geomorphology

Fluvial Landforms

Surface water acts as a destructive agent, weathering and eroding the landscape by carving river valleys. Sediments are entrained, transported downstream, deposited, and stored in the landscape as a variety of landforms, such as floodplains, deltas, and alluvial fans. Floodplains are formed by the accretion of sediments deposited by river migration or flood processes. Deltas form when a river encounters a body of water, its velocity slows, and its ability to carry sediment diminishes. Deltas can form in dammed lakes, at tributary confluences, or at the mouths of rivers encountering the ocean. In arid regions, alluvial fans are formed when a river draining from a mountain range encounters a change in gradient and its ability to carry sediment is reduced. The transported sediment is deposited as an alluvial landform, which often exhibits a classic fanlike shape.

Glaciers

Surface water in glacial form (alpine and continental) is a significant erosional and depositional force. As glacial ice flows downhill, it abrades, plucks, transports, and deposits glacial sediments into linear ridges, called *moraines*. When alpine glaciers recede, the V-shaped character of previously stream-dominated mountain valleys is replaced by the characteristic U-shape of a glaciated trough, and numerous landforms such as hanging valleys, horns, and paternoster lakes are left behind. Glacial meltwater in both alpine and continental contexts also creates unique landforms: outwash plains, eskers, and kettles, to name just a few.

Coastal Landforms

Oceans create unique shoreline and coastal landforms by reworking and redistributing coastal sediments through wave refraction and longshore currents, producing a variety of depositional and erosional landforms. The former include features such as bars, spits, and barrier islands, while the latter include wave-cut terraces, wave-cut scarps, and arches.

Surface Water and Humans

Surface water is an important factor in human activities. Rivers have led to the colonization of continental interiors, are used in military strategy, and provide the means to transport products to the market. The global economy relies on the presence of surface water to transport large quantities of consumable products. Ocean transportation moves billions of cubic tons of goods and resources throughout the globe each year.

Irrigated Agriculture

Due to the practice of irrigated agriculture, surface water has played a defining role in the diaspora of humans throughout the globe. Cultural groups have arisen around the practice of moving surface water through human-made channels and waterworks, thus furthering the settlement of arid regions otherwise uninhabitable by humans. The earliest origins of irrigated agriculture lie in the Middle East; however, it has also arisen independently in the Far East and in the Americas.

Dams

Dams impound surface water for regulated release downstream and are used for flood control, public water and fire suppression supply, recreation, and electricity generation. Dams fragment watersheds by changing the natural flow of rivers and causing significant changes to upstream and downstream hydrology, riparian ecosystems, water chemistry, and fluvial landforms. The reservoirs created by dams may be sizeable enough to affect the local climate. Although dam construction peaked in the 1970s in the United States, the amount of water currently stored behind dams can spatially cover a surface area the size of France.

The Effects of Global Climate Change on Surface Water

Surface water is a renewable resource and the primary source of global public water supply. Currently, there is sufficient surface water to support the ever-increasing global population, but the geography of that water will continue to be a challenge, as global climate change is altering its distribution

and availability. As glacial ice around the globe melts as a result of climate change, significant effects on surface water are becoming evident. In mountain environments, glaciers, which provide important meltwater for the local ecosystem, public supplies, and irrigation, are diminishing. In many areas, river flows resulting from this melting are volumetrically less than their historic flows. Over one sixth of the world's population depends on this water for its daily needs, and concern about future availability is growing. As the continental glaciers melt, the introduction of freshwater to the saline oceans is predicted to affect global circulation patterns. Sea-level rise in response to global climate change also has the potential to create a variety of hazards, as 10% of the world's population lives within 150 miles of the coast.

SURVEILLANCE

Surveillance is the practice of watching over a given terrain, its inhabitants, and their relations, commonly for the purpose of exercising instrumental control over that which is being watched. As such, surveillance is central to the establishment and maintenance of “scopic regimes” that enact power to order the world. From its inception as a discipline, and indeed even prior to its attainment of disciplinary status, geography has engaged with surveillance as both participant and observer.

Observing the distribution of human and natural variation across the surface of the Earth, and reporting on that variation, has been a key geographical practice from the times of Strabo through those of Ibn Battuta, John Mandeville, Xu Xiake, and beyond. Such accounts tend to be cartographical exercises conjoined to richly descriptive, and sometimes apocryphal, travelogues. A subset of these, however, serves the additional purpose of providing rulers and their administrative bureaucracies information on the presence and distribution of resources in given territories. Such information, in turn, informs the policies and actions by means of which rule may be imposed on the ground.

But the rise of the European empires, and the corollary entrance into an “age of reconnaissance,” required an unprecedented demarcation of new territories and the cataloguing of their contents. This not only heightened the prominence of expeditionary surveys but was, to no small extent, dependent on them too. Geographers and their explorations, as, for instance, those of Alexander von Humboldt, Richard Francis Burton, and Piotr Kropotkin, were at least initially charged with and supported by the task of seeing for empire building. Empires in turn claimed and asserted, however incompletely in practice, a mastery over all that they saw in no small part through the lenses of such expeditions. This process contributed centrally to both the legitimization and the elaboration of geography as a discipline.

The role of surveillance to fix things in space was complemented by the fixing of attributes to things—the application of categories to that

which was surveyed and the ascription of fixed attributes to these categories. Thus, the expeditionary practice of geography did not merely undertake surveillance but created surveillability, rendering that which was seen recognizable within a disciplined system of spaces understood as both substrate and container. Outgrowths of this process ranged from intricate and intimate catalogs of a given locale’s vegetal and mineral resources to cut-and-dried global mappings of the distribution of the world’s putative races.

Although it was developed and deployed most extensively at and beyond colonized peripheries, intensive geographical surveillance was quickly repatriated back to core territories and, most prominently, to the metropolis. With the rise of the modern state, surveillance was key to the concomitant transformation of subjects into manageable, governable populations. This was accomplished through the innovation of initially geographical sciences, such as demography and its allied statistics, and their implementation through a range of practices, such as the mandatory assignation and stabilization of surnames conjoined to the conduct of increasingly regular censuses. Nor did these innovations remain conceptual abstractions or occasional events. Rather, they were palpably and even immutably materialized on the ground to facilitate state functions such as policing and fire suppression, as with the 19th-century parcelization of Berlin into courtyard apartments or the still extant ward system of Edo (now Tokyo).

Grand expeditionary surveys are now largely a thing of the past. The impetus for intensive and extensive surveillability, however, has continued unabated and, if anything, intensified in recent years. This drive toward *panopticism* (the capacity to readily see into all places) and *synopticism* (the capacity to see everything simultaneously and in relation) has in turn been facilitated by, and spawned, a host of new technologies. Most notable among these, at least from the demonstrated perspective of contemporary geographical research, are those of geographic information systems conjoined to remote sensing (GIS/RS) and closed circuit television (CCTV) monitoring. But equally notable is the shift in the perspectives and roles of many geographers themselves from collaborators in surveillance to critics of it.

GIS/RS is a relatively novel complex of technologies ranging from satellites to desktop computers. Predominantly a research tool, this complex is targeted and interfaced so as to gather, process, and graphically represent data pertaining to the disposition of selected objects and attributes at discretionarily specified points across the face of the Earth. In contrast, CCTV has emerged predominantly as a tool of law enforcement, consisting of numerous observation cameras dispersed across commonplace landscapes so as to insert an unprecedented reach of centralized observation into the spaces of everyday public life.

Neither technology is necessarily oppressive, and both provide opportunities for creative and even emancipatory use. For example, GIS/RS affords a potential for wide public access to, comprehension of, and intervention in geographical data gathering and the application of such data to

popular decision making. Similarly, the devolution of CCTV's observational capacities into compact and affordable handheld devices permits unprecedented opportunities for popular monitoring of, and reporting on, public malfeasance. But taken together, and fused with innovations such as states' and business corporations' monitoring, databasing, and mining of electronically mediated personal interactions, these technologies work to embody what many geographers caution is becoming a "society of surveillance." Inherent in such a society are radical loss of privacy and the potential for severe new delimitations to permissible ranges of action, expression, and even thought. Furthermore, geographers warn, these ominous possibilities are becoming ever more concrete and rhetorically legitimized realities in the diffusing wake of terrorist activity and the concomitant, putative war on terror. As such, surveillance is

increasingly understood as not just the practice of watching over but as something that itself needs to be carefully watched over.

SURVEYING

Surveying is the art, science, and technology of determining or establishing the three-dimensional (3D; x , y , z) position of points on or beneath Earth's surface. Because geographic surveying deals primarily with topography, two other terms, *topographic surveying* and *field surveying*, are interchangeably used. Geographic survey data are used to produce topographic maps, block diagrams, and cross-sectional profiles and to establish vertical and horizontal controls such as spot heights and benchmarks.

Conventional geographic surveying uses theodolites, levels, chains, links, steel (or invar, a steel alloy) tapes, altimeters, compasses, clinometers, tachymeters, stadia rods, plane-table alidades, ranging poles, tripods, and the total station. Three basic sets of readings are taken during a conventional survey: distances, heights, and angles. Horizontal distance can be measured with a tape using slope distance and reducing it to horizontal distance using the cosine of the slope gradient. Elevation (height) is measured using a leveling instrument with a level telescope and a stadia rod or by observing the vertical

angle with a clinometer and deriving height. The horizontal angle is measured with a compass. Direction is expressed relative to a reference line (meridian). A North-South line is the true meridian, although a magnetic meridian may be used if compass azimuths are recorded without adjusting for declination.

The total station is the instrument of choice for many topographic surveyors because it integrates theodolite functions and an electronic distance meter (EDM) with a built-in or external computer for data storage. Its capability to automate and integrate the measurement of distances, heights, and direction greatly improves topographic surveying and mapping.

In any conventional survey, the starting or initial position(s) must be known and must be accessible. Subsequent positions are observed and determined based on preceding point base positions. There are four common approaches used in surveying—namely, triangulation, trilateration, triangulation, and traversing. In triangulation, the location of a point is determined by measuring the angles to it from the initial points at either end of a fixed baseline rather than measuring the distances to the point directly. The point can then be fixed as the third point of a triangle with one known side and two known angles. Triangulation is used in surveying large areas for geodetic purposes. Trilateration is used in conjunction with triangulation to determine the intersections of three sphere surfaces given their centers and radii. Triangulation is a combination of triangulation and trilateration. *Traversing* is the establishment of a series of consecutive lines (legs) and directions whose ends define points (also called *stations*, *hubs*, or *corners*).

There are four main types of traverse: link (azimuth), closed loop (polygonal), closed, and open (free). A link traverse follows along a single direction (azimuth). This method is common for slope profile surveys and is always perpendicular to the contours. Closed-loop traverses begin and end at the same station. In this method, interior and deflection angles can be established. A closed traverse uses a known endpoint, and its exterior angles can be measured. An open traverse ends in an unknown position.

Inaccuracy in surveys is a common problem. Sometimes even closed traverses will not “close”

A road surveyor checks the land on the road construction site in the Dhi Qar Province, Iraq, July 3, 2005. The U.S. Army Corps of Engineers provides quality assurance on the road project.

Source: U.S. Army photo by B. J. Weiner.

because the initial point and the endpoint fail to coincide. This error is called the *closure error* (gap). Closed-loop and closed traverses permit calculation and adjustment for closure error. However, it is more difficult to maintain good accuracy in an open traverse, as it does not enable computational checks for error.

Error is related to the quality of the equipment, the nature of the terrain, and the skill level or experience of the surveyor. The amount of error that can be tolerated (degree of tolerance) is a function of the order of accuracy desired, which in turn depends on the intended use of the survey data. Accuracy is expressed in terms of the proportion of the traverse length, stated as $1/x$: For every x units measured, the survey should be off by 1 unit. First-order

accuracy = $1/25,000$, second-order accuracy = $1/10,000$, and third-order accuracy = $1/5,000$. In a typical topographic survey, the desired level of accuracy is the plottable error—the shortest distance that can be depicted on a map at a given scale. The drafting of lines generally is accurate to within 0.25 mm (millimeters). Survey errors are minimized by conducting quality surveys, repeating measurements in the field, using calibrated instruments, and adjusting and correcting measurements. Several standard survey correction formulae spread the closure error to all angles and legs, especially in closed-loop and closed traverse.

The introduction of the global positioning system (GPS) has revolutionized surveying. GPS is capable of determining positional and navigational information accurately and instantaneously. Two positioning methods can be achieved with the GPS: absolute and differential GPS (DGPS). Absolute positioning uses a single GPS receiver and does not require known survey control points. DGPS uses at least two GPS receivers.

One is the reference receiver (base station), resident at a known location. The other receivers are used in the field to position points of interest. Both absolute positioning and DGPS can be performed in real time or through postprocessing. Real-time positioning is achieved by effecting communication links between the field receiver and an augmentation system. The method of choice depends on the accuracy required, the equipment available, and the logistical requirements. Accuracy in GPS survey is a function of the quality of the equipment and the surveying method employed—absolute positioning or DGPS. DGPS is the more accurate. The use of GPS has added efficiency and productivity to surveying.

SUSTAINABILITY SCIENCE

The growing recognition that human activities are transforming Earth systems and having far-reaching implications for society has given rise to the ambitious research field of sustainability science. This area of study is concerned with the most complex challenges that societies face, focusing on the dynamic interaction of nature-society systems in response to stresses emanating from multiple sources. Sustainability science grapples with societal problems that are characterized by multiple viewpoints and a high degree of uncertainty. It evolves from a scientific perspective of critically examining the relationship between nature and society. It addresses tensions among economic, social, technological, and environmental interests among a broad range of stakeholders while focusing on interactions across scales. Though sustainability science has not been clearly defined, in recent years, its central elements have begun to gain clarity; hence, the field has begun to be recognized as an area of inquiry that can point the way toward sustainable development. The field has focused on the nature of a sustainability transition, described by the U.S. National Research Council (NRC) as meeting the needs of

a stabilizing future population while reducing hunger and maintaining Earth's life support systems. This entry synthesizes the emerging scholarship on sustainability science in its quest for a societal transition toward sustainable economic development.

Emergence of Sustainability Science

Sustainability science reflects several decades of scholarship in the fields of natural resource sciences and technology. Indeed, the use of the term *sustainability* can be traced back to a 1712 book, *Sylvicultura Oeconomica*, by the German scientist and forester Hans Carl von Carlowitz. Intellectual contributions on sustainability also come from pioneering scholarship on human-environment interaction by the geographer and anthropologist Peter Glacken in his seminal work *Traces on the Rhodian Shore*, the work of the agricultural economists Yujiro Hayami and Vernon Ruttan on land-saving and yield-enhancing technologies, and the insights from Earth-friendly and user-friendly technology, also termed *appropriate technology*, following the economist E. F. Schumacher's publication of his famous book *Small Is Beautiful*. However, a more academic perspective on sustainability emerged during the environmental movement of the 1970s as well as from the seminal document *The World Conservation Strategy*, published by the International Union for Conservation of Nature in 1980.

Much of today's work on sustainability science is inspired by the landmark Brundtland Commission report on sustainable development, published in 1987 by the World Commission on Environment and Development (WCED). This report argued that the complex challenge of environmental degradation should be integrated with the equally complex challenges of human development and poverty alleviation, suggesting that both challenges need to be resolved simultaneously and in a mutually reinforcing way. Additional impetus to sustainability science was given at the 1992 United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro. The conference's Rio Declaration and Agenda 21 together developed detailed strategies, action plans, and resource needs for attaining sustainable development in the 21st century.

While Agenda 21 exhibited a much needed political and moral appeal, the global community remained divided about the meaning and practice of sustainability. The United Nations Commission on Sustainable Development (UNCSD), established in the wake of the Rio conference to monitor and report on the agreement reached in Rio, provided a sobering appraisal of the first decade of the effort to realize the vision of sustainable development in the 1997 Special Session of the United Nations General Assembly. The report concluded that no significant progress had been made on the sustainable development front despite the limelight that the concept received at the global meeting.

In the ensuing years, the terms *sustainability* and *sustainable development* were revisited and redefined to establish a conceptual basis and to encapsulate various aspects of society and environment relations. In their report *Our Common Journey*, the Board on Sustainable Development of the U.S. National Research Council outlined a scientific agenda and a general strategy for research and development (R&D) in support of the transition to sustainability. Although the report did not describe paths of sustainability science, it concluded that many of the most problematic threats to society and its life support systems come from the multiple stresses resulting from cumulative human activities. This conclusion was significant in that it recognized the value of studying the multiple drivers of environmental and social stressors. More specifically, the report emphasized a move toward a more holistic approach for addressing sustainability challenges by taking into account the dynamic and complex interactions among human-environment systems. The report also laid a much needed foundation for R&D in sustainability science.

During the succeeding years, the discussion about the role of R&D in the sustainability transition, particularly in science and technology (S&T), intensified. This discussion began involving researchers, practitioners, academics, citizen forums, and development and nongovernmental organizations (NGOs) worldwide. When the World Summit on Sustainable Development was held in Johannesburg (2002), consensus was forged on the most important ways in which R&D could contribute to sustainability. The

message emerging from Johannesburg was that the scholarly community must contribute to identifying problems of sustainability with a greater willingness to join the nonacademic communities to work on practical solutions to the challenge of sustainability. While various disciplines and interest groups influenced and contributed to the debate differently, the global challenge of sustainability is now understood to lie in the complex interdependencies of environmental, social, and economic development across scales. Moreover, though threats to sustainability occur more in some regions than in others, the degree and extent of any threat depends largely on the region's social, political, economic, and ecological characteristics. For this reason, the transition to sustainability will often need to happen in local areas first. At the same time, however, it needs to be integrated across geographic scales. Regardless of the spatial scale in question, obtaining insights into events on both global and local scales will continue to be a major challenge facing sustainability science. Thus, a transition to sustainability ultimately rests on the choices that society makes on what to develop versus what to sustain and for how long.

Conceptualizing Sustainability Science

The epistemology of sustainability science draws largely from the study of the Earth and Earth's social and human systems and is characterized by great complexity and uncertainty. Given the nature of such complexity, system thinking has become a way of understanding reality that emphasizes the nonlinear relationships among the different system components. In pursuing sustainability science, it is important to construct a knowledge platform that enables society to replace piecemeal approaches with an approach that can develop and apply more comprehensive solutions to the challenges that society is facing. Structuring knowledge production systems across the global, social, and human systems (discussed below briefly) is therefore an important task of sustainability science.

According to Hiroshi Komiyama and Kazuhiko Takeuchi, the global system constitutes a planetary base for human survival. It is capable of influencing the entire network of Earth systems

and can have severe implications for human existence. Conversely, the rapid expansion of human activities has become a significant driver in altering Earth's systems. Global warming due to increased concentrations of greenhouse gases, destruction of the ozone layer, and biodiversity loss due to land use and land cover change are salient examples of global change that are the outcomes of human and social systems. Given these developments, addressing global systems requires a more integrated approach, for which sustainability science offers a greater potential.

The social system consists of cultural, political, economic, and other institutions that are an important basis for driving economic growth and development. Existing institutions, however, are associated with environmental ills such as degradation of the natural resource base and are also responsible for creating the growing inequality between the rich and the poor. The integrated nature of this situation is responsible for exerting greater stress on global systems. If sustainability science is to be policy relevant, it is important to address both environmental and social issues simultaneously. By incorporating social science into sustainability issues, sustainability science can make major advances in the pursuit of sustainable development.

The healthy functioning of human systems requires the integration of global and social systems in a manner that enables human beings to thrive and sustain their communities. In today's world, people are experiencing emotional distress, inequities, and deterioration of their means of production. Such problems put pressure on social and environmental systems worldwide. As this stress increases and the environment deteriorates, the social system becomes more fragmented, making human society less sustainable—all of which can have a global effect. Emblematic of this trend are the problems of extreme poverty, disease, social exclusion, and conflicts, weakening the sustainability of human systems.

Thus, the emerging field of sustainability science is an ambitious attempt to build a new discipline that seeks to integrate all three systems. Since sustainability science requires integration of multiple and complex systems, system thinking has a special role to play. System thinking helps actors to see the various elements of systems and

cross the boundaries of science in order to create new conceptual frames that highlight interconnectedness and feedback loops. It also offers a powerful perspective and a set of tools to address the most complex challenges facing human society. Efforts to provide useful knowledge for solving the practical but highly complex problems discussed above require advances in the conceptualization and understanding of coupled human-environment systems. While strategies to address the emerging threats of global climate change, governance of emerging technologies, poverty, and hunger are all complex sustainability challenges, the potential exists to galvanize global action to place sustainability science at the forefront of educational, research, and career development agendas. In recent years, rising concerns over global climate change, the conservation of ecosystem services, biodiversity protection, diversification of energy portfolios, improving efficiency and access to water supplies, and enhancing agrobiodiversity and food security have become important priorities of sustainability science.

The conceptual model for sustainability science can be represented as “coevolution,” “coproduction,” and “colearning,” encompassing the three interrelated systems discussed above. This conceptual model is inspired by what researchers call “Mode 2,” or “postnormal,” science. According to Pim Martens, “Mode 1” science is conventional and purely academic and focuses on single disciplines to generate its knowledge base. The researchers who are involved in this process are the major players. In Mode 2 science, researchers are part of a heterogeneous social network focusing on social and anticipatory learning, where everyone contributes to knowledge production and dissemination. In other words, Mode 1, or conventional science, as opposed to Mode 2 science, is predictive and seeks to rationalize certainty, a desirable goal for policy making. Mode 1 science is thus characterized as deterministic and is often disconnected from the challenges facing the real world. Mode 2 science, in contrast, acknowledges that the complete elimination of uncertainty is not possible in decision making and argues that this can be addressed through participatory processes in knowledge production, an idea completely rejected by Mode 1, or rational, science. Postnormal science provides a

well-informed knowledge platform for complex problems, thereby enhancing the interface between science and society. It allows stakeholders to identify and employ strategies that will respond to the transition toward sustainability.

As opposed to Mode 1 science, which generally holds the notion of the community as a passive recipient of knowledge, Mode 2 science leans on the conceptual underpinning of social and anticipatory learning and emphasizes the study of interlocking factors embedded in the socioeconomic and political fabric of communities to understand strategies for sustainability at the local level. It highlights inherent community-based skills, knowledge, strategic responses, and anticipatory capacity to attain sustainability and seeks the cooperation of local institutions and/or individuals in the process. It is through this process of social and anticipatory learning that Mode 2 science fosters a community's capacity to influence its future through iterative planning.

The new research paradigm emerging from Mode 2, or postnormal, science has given impetus to sustainability science, which cuts across multiple scales (time and space) and multiple stakeholders (interest groups). Sustainability science seeks to integrate not only different disciplines but also individual viewpoints and knowledge so that the scientific processes of deliberation and assessment are smoother. And no one set of knowledges or viewpoints is privileged over another. The new frontier of sustainability science also recognizes the value of alternative knowledge systems that have hitherto been neglected by scholarly communities. It differs from normal academic science, which is monodisciplinary in nature and heavily dependent on peer reviews by the scientists themselves.

As an emerging field of study, sustainability science is not yet a discipline. It is the interface of science, practice, and visions of sustainable development. Given the integrated nature of this field of study, the research framework in sustainability science derives its methodological tools from all fields of inquiries, including the social, human, and natural sciences. So the core organizing questions for sustainability science are as follows: How best can global, social, and human systems be integrated and conceptualized so that the goal of sustainable development is attained? How is

the societal relationship with the environment and development reshaped by innovations of science and technology? What contextual factors hinder the path toward sustainable trajectories, and what incentive structures can do that most effectively? How can today's knowledge systems, which are locked in across various cultures and traditions, be harnessed to provide more useful guidance for efforts to navigate a transition toward sustainability? How can today's relatively independent activities of research planning, monitoring, assessments, and decision support be more integrated into systems of social and anticipatory learning?

Sustainability Science: Basic or Applied?

One of the major characteristics of sustainability science is that it seeks the involvement of nonacademic stakeholders in the integration of human and social systems with the global system and aims to integrate different norms and values in order to generate socially acceptable and environmentally just knowledge about sustainability. It challenges traditional concepts and institutions of scientific knowledge generation and serves as an experiment in a new model of science. It recognizes the value of supporting interdisciplinary research and is driven by the goal of creating integrated knowledge that supports decision making for sustainable development. As an integrated science, it seeks to break down the disciplinary boundaries of the traditional sciences and calls for mutual learning, integrated assessment, and coproduction of knowledge. From its core focus of advancing an understanding of coupled human-environment systems, sustainability science has, in a short time period, pursued an ambitious research agenda that challenges academic traditions with respect to fundamental ontological (real-world problem orientation), methodological (participatory research), and epistemological ("linking knowledge to action") issues. In its quest for transition toward sustainability, sustainability science seeks to harness S&T in order to address the sustainability challenges of the human-environment system.

In his seminal treatise on science policy, Vannevar Bush described the conflict between applied and pure research and wrote that applied research

invariably drives out pure research to the detriment of the national capacity for technological innovation. The subsequent separation of applied and basic research shaped the evolution of S&T research and remained a point of departure for the “appropriate technology” movement pioneered by E. F. Schumacher. The rise of pure science research also meant the neglect of what Michael Dove and Daniel Kammen call “mundane science,” which involves the use of location-specific knowledge and small-scale technologies that are problem driven with potential advances to pure science. The inability of pure science research, with its disciplinary focus, to address myriad social concerns led to a growing recognition of the value of interdisciplinary research. This can be seen as a precursor to sustainability science that involved identifying important but neglected fields of research and scholarship.

William Clark has argued that the research framework for sustainability science lies beyond the confines of basic and applied research. Just as sustainability science has reached out to contribute to and learn from the world of applied problem solving, so, too, has it remained closely linked with curiosity-driven research across a range of disciplines. It is an academic endeavor that is geared toward use-inspired basic research and is driven by the integration of knowledge and action across the three systems discussed earlier. By bridging applied and basic research, sustainability science advances the interface between science and policy. Since the issues and problems that sustainability science tackles are interdisciplinary in nature, it involves different stakeholders and actors from different disciplines and requires their collaborative inputs. Thus, interdisciplinarity becomes the hallmark of research orientation in this field. This has meant that scientists seeking to promote a sustainability transition have needed to tap into, and indeed engage in, cutting-edge research in areas ranging from complex systems theory to cultural and political ecology. Sustainability science is an academic enterprise geared toward creating use-inspired research and is therefore neither strictly “basic” nor strictly “applied.” By creating a dynamic bridge between applied and basic research, sustainability science seeks to contribute to the quest for a sustainability transition by increasing the interface between knowledge and policy-based action.

Conclusion

Sustainability science is an integrative science that is interdisciplinary in nature and committed to linking different scientific disciplines such as biology/ecology, the Earth sciences, geography, economics, and other social sciences to provide a guide to science policy for society. Through interdisciplinary research and scholarship, sustainability science helps identify directions for societal actions. The outcomes of sustainability science can bridge the gap between science and policy, which increases the societal value of science and improves decision making through the provision of integrated knowledge about social and environmental problems. Sustainability science must ensure the integration of different styles of knowledge creation to bridge the gulf between science, practice, and politics. Through research, publications, and academic organizations, the field of sustainability science is becoming increasingly prominent in academia. It has the potential to transform research and education and make sustainability an integrated and common theme for scholars, policymakers, and civil society actors alike.

fossil fuels—and politicians, agribusiness leaders, environmentalists, and farmers alike now advocate for “sustainable agriculture.” However, sustainable agriculture is a poorly defined and highly politicized term, and it clearly means different things to different stakeholders. This is because sustainable agriculture is a philosophical approach, rather than a specific production system, that promotes social, ecological, and economic health in food- and fiber-producing lands and communities. A diversity of locally based low-input and knowledge-intensive farm systems exist that follow the principles of sustainable agriculture. As these holistic approaches to cultivation and animal husbandry are further refined and communicated, their legitimacy and widespread adoption is inevitable.

Agriculture's Roots

It is generally understood that agriculture was born around 10,000 to 13,000 years ago, when hunter-gatherers began to domesticate wild plant and animal species for food, predominately along the Fertile Crescent, an event called the Neolithic Revolution. By domesticating plants and animals, these “first farmers” produced food surpluses that supported permanent settlements, which led to rapid population growth, specialized labor, and the development of modern civilization. Agriculture has radically transformed humanity's trajectory as a species and its relationship with and impact on the natural world, creating many opportunities and challenges, especially over the past century.

SUSTAINABLE AGRICULTURE

Agriculture has had a profound impact on the natural world, especially over the course of the 20th century. In many places, agriculture is now increasingly industrialized, leading to monocultures that are reliant on external mechanical, biological, and chemical inputs (e.g., tractors, hybrid seeds, and pesticides). Many geographers and others are beginning to question the sustainability of these conventional systems. Indeed, industrial agriculture has hit a crisis point—especially when considered in combination with the issues of environmental erosion, climate change, and depleting

The Rise of Industrial Agriculture

The rise of industrial agriculture in the 20th century—predicated on mechanical, biological, and chemical technologies—exceeded in magnitude all previous changes in farming. Governments and industry promoted industrial agriculture, as it was their belief that Fordist principles of manufacturing and large-scale production could be applied to agriculture. After World War II, the chemicals developed for military activities were subsequently used in agriculture as synthetic pesticides and fertilizers, and in combination with tractor power, these inputs dramatically increased labor and land productivity.

Farmer-led plant breeding was quickly replaced by expert-based approaches using the new science of genetics, leading to the development of hybrids and other high-yielding and high-input varieties that were distributed worldwide during the Green Revolution. The discovery of antibiotics and vaccines enabled industrial-scale livestock production—often called “factory farming”—in which animals are raised in densely crowded spaces without a significant buildup of disease. Indeed, industrial agriculture increased global food production and helped feed and ultimately increase the world’s human population, now estimated at 6.8 billion people. Despite these significant production benefits, industrial agriculture has caused substantial social, ecological, and genetic erosion worldwide.

Social, Ecological, and Genetic Erosion

The shift toward industrial agriculture has had adverse consequences for farmers, rural communities, and the environment. Many suggest that farmers have become beholden to a “technology treadmill” with the rise of mechanical, biological, and chemical innovations, as increases in production depress prices and require that farmers adopt ever newer technology to stay competitive. Larger farms have generally been able to adopt new technology more easily, which has created fierce competition within rural communities, and many smaller family farms have not been able to stay viable. High input costs remain the number one obstacle to farm profitability. In North America, farmers are facing the worst farm income crisis in history, with the countryside being increasingly depopulated, while agribusiness has garnered record profits. In the global South, reports of farmer suicides are becoming pervasive, as mounting debts tear apart the social fabric of many communities. The environmental costs of industrial agriculture are also placing enormous pressure on human and ecological systems.

Rachel Carson’s publication of the best-selling book *Silent Spring* in 1962 exposed the extent to which chemicals, primarily those used in agriculture, were compromising environmental and human health. Globally, the use of pesticides has grown since World War II, costing billions of dollars annually and causing thousands of human

deaths and adverse health risks due to cancer, acute poisonings, and neurological damage each year. Pesticides also harm a wide variety of wildlife, including microorganisms, fish, birds, and mammals, through direct or secondary environmental exposure. Estimates indicate that this chemical pollution from agriculture costs more than \$100 billion each year in human health and environmental damage worldwide. Soil health, which is critical for food production, has also been damaged by industrial agriculture due to increasing farm specialization, ever-larger farms, and monoculture cropping practices. Because of the use of inorganic fertilizers, the natural organic matter of the soil is not being replenished; thus, despite these chemical substitutes, soil has lost its productivity, resulting in major yield decreases. Some even argue that excessive soil damage has caused the downfall of past civilizations and may cause the downfall of the modern era.

With the increased use of pesticides, some insects, weeds, and fungi evade being controlled and eventually evolve resistance. These “superpests” are often difficult to control, leading some to conclude that chemicals might actually create greater pest problems than they solve. Similarly, the overuse of antibiotics in industrial livestock production is a global concern, given that agricultural pathogens are becoming antibiotic resistant and are being passed to humans via the food chain, which causes health risks and reduces the efficacy of important antimicrobial drugs. These problems are further compounded by the overall loss of genetic diversity in agriculture. To overcome superpests, plant breeders increasingly use genetic materials from locally adapted nonindustrial varieties, as these traditional landraces often have natural pest resistance. However, with the development of scientific breeding programs, many of these landraces were domesticated, and their genetic diversity has been irrevocably lost. As industrial livestock production favors “high-performing” species, many traditional breeds are now becoming endangered and extinct, and this combined loss of livestock and crop agricultural biodiversity is a major global problem. Indeed, agricultural systems that promote social, ecological, and economic sustainability are desperately needed, especially given the environmental and energy challenges of the next decade.

Sustainable Agriculture: From Crisis to Opportunity

In an era of global climate change and depleting fossil fuel, industrial agriculture is increasingly recognized as being very energy inefficient, and this has been deemed its “Achilles’ heel.” Industrial agriculture requires external energy inputs in the form of fossil fuels for tractors and irrigation, petrochemical-derived fertilizers to increase yields, and massive energy requirements to transport food globally. In an era of environmental awareness and concern, industry, governments, farmers, and the public largely agree that sustainable agriculture is desirable. However, sustainability is a contested term, and how it is to be achieved in agriculture remains elusive if not controversial. This is because sustainable agriculture is a philosophical approach, rather than a specific production system, that promotes social, ecological, and economic health in food- and fiber-producing lands and communities. Any agricultural system that is financially and socially prosperous, knowledge intensive, and based on renewable, low-input, and locally based resources is generally considered sustainable. Arguably, the crisis in industrial agriculture has created a necessary opportunity for those countries practicing it to transition to sustainable approaches, and there is no better example of this than Cuba.

The Cuban Experience

The most successful demonstration of the transition to a low-input, self-reliant, and knowledge-based agriculture has taken place in Cuba, which is a world leader in sustainable agriculture. After the fall of the USSR and the continuing U.S. trade embargo, Cuba was largely unable to import either food or the chemicals, fertilizers, fossil fuel, and machines required for the agricultural sector, which at that time was technologically comparable with that of California. Although the crisis initially caused drastic yield reductions in the country, small-scale farmers quickly increased their domestic production, largely by relying on their local knowledge of preindustrial farming techniques such as intercropping, plant breeding, animal traction,

manure spreading, and composting. This success led the government to downsize its industrial-scale state-owned farms, which it gave to farmer cooperatives to manage using their knowledge of low-input and ecology-based agriculture. Technology was developed that supported this transition, and government scientists developed new, ecologically friendly biopesticides and biofertilizers to support the efforts of small-scale farmers. Furthermore, in Havana and in other cities, urban farm and greenhouse initiatives were implemented to create local food security and employment in the most populous regions. Cuba stands as an example of how farmer knowledge, political will, and appropriate technology can be combined to overcome a crisis and create sustainable agriculture and food self-sufficiency.

“Alternative” Agriculture

Sustainable agricultural systems are often referred to as alternative, yet this is a misnomer, as these approaches are actually quite normal and are practiced by millions of farmers worldwide. In Africa, Asia, and Latin America, many farmers have increased their yields, provided for their families, and enriched their communities while being stewards of the land without having adopted high-cost external inputs. Many farmers in North America, Europe, and Australia found that industrial agriculture was making their operations unviable, and they have successfully and sustainably reverted back to older ways of farming that predate the introduction of synthetic pesticides and fertilizers. Indeed, many farm systems around the world exist that subscribe to the philosophy of sustainability.

Approaches that follow the principles of sustainable agriculture include organic farming, biodynamic farming, agroecology, holistic management, urban agriculture, community-supported agriculture, and natural systems agriculture, among others. Diversity is the strength of sustainable agriculture, and many of these systems are used in combination, which allows for a holistic piecing together of the necessary yet complex social, ecological, and economic components of sustainability. The overwhelming similarity among sustainable agricultural systems is that

An Alaska landowner and the district conservationist Phil Naegele discuss management of a sustainable agriculture lingonberry field. Landowners use waste from a local fish cannery as fertilizer.

Source: Ron Nichols, U.S. Department of Agriculture, Agricultural Research Service.

they rely on local knowledge and are ecologically regenerative. Farmers' local knowledge represents a rich and reliable source of information on agroecosystems and helps replace the costly external inputs of industrial agriculture. It is experience based, place specific, and holistic in nature, and it enriches and complements scientific data. In sustainable agricultural systems, farmers' local knowledge often improves and increases nutrient cycling and associated productivity, self-reliance and profitability, and conservation of soil, water, energy, and biological resources. This is achieved in combination with the reduction or elimination of external, nonlocal, and nonrenewable inputs, which often have associated financial and environmental costs. Sustainable agricultural systems are often labor intensive, requiring many skilled and committed

people to contribute to these farms, which in turn leads to populated, vibrant, and socially cohesive rural communities.

Sustainable agricultural approaches are not low technology or "neo-Luddite," as they can incorporate both scientific and farmer knowledge and can be adopted by a diversity of farmers. Farmers, agroecologists, and plant breeders working together at The Land Institute in Salina, Kansas, are developing "natural systems agriculture," which is a model of food production that mimics the prairie ecosystem. They have been breeding perennial versions of major annual grain crops and growing them in polycultures, which reduces the need for tilling, uses few chemicals, and creates a food system that regenerates every year. Importantly, any farmer worldwide—regardless of current practices, motivation, skill,

and knowledge—can incorporate sustainable agricultural approaches into existing operations. Indeed, many people subscribing to the values of sustainable agriculture will be required to participate in future food production.

The Future of Food Production

Worldwide, both farmers and consumers increasingly recognize the importance of sustainable agriculture for society and the environment, especially given the ecological and energy crisis facing humanity and the planet. As the sustainable agricultural movement continues to grow, it will be rooted in values that promote diversity and social, ecological, and economic health and prosperity for the land and its communities.

- Pretty, J. (Ed.). (2005). *Sustainable agriculture*. London: Earthscan.

Initially, local governments were considered, from the economic and political points of view, as the most ill suited to resolve major and expensive environmental and social problems. However, in the agreements reached at the United Nations Conference on Environment and Development (the Earth Summit) held in Rio de Janeiro in 1992, it was established that many of the problems and solutions being addressed by *Agenda 21*, have their roots in local activities. Thus, the participation and cooperation of local authorities would be a determining factor in meeting such objectives. In this regard, it was affirmed that local authorities should maintain and promote economic, social, and environmental infrastructure; inspect urban planning projects; develop and implement local environmental policies and laws, and assist other supramunicipal administrations in implementing other environmental policies. As the administration closest to the people, they have to foment citizenship education to promote sustainable development.

The European Conference on Sustainable Cities and Towns, held in Aalborg, Denmark, in 1994 and organized by the International Council of Local Environmental Initiatives (ICLEI), approved the Aalborg Charter. This establishes that the objective of European sustainable cities is to achieve social justice, sustainable economies, and environmental sustainability.

According to the Charter, social justice will necessarily have to be based on economic sustainability and equity, which require environmental sustainability. Socially, cities should create a cooperative environment where unemployment, deprivation, and underachievement are absent and where economic development is compatible with respect for social rights. This will promote an environment where social integration—that is, the compatible cohabitation of racially, culturally, and socially diverse groups—is a reality and where, at the same time, the quality of life for all segments of the population has improved.

Environmentally, cities should use resources ethically, which means that they should minimize their consumption of resource inputs from outside the community and minimize the production of waste outputs. They must also create a society based on renewable energy, complete cycling of resources, no use or release of toxins,

SUSTAINABLE CITIES

A sustainable city is one that while providing a high quality of life to a diversified and plural society in the present, establishes the mechanisms necessary to ensure suitable economic and social growth in the long term while maintaining the natural resources of the environment. This will allow future generations of citizens to satisfy their needs on the same terms.

and development as the restoration and enhancement of the environment's and economy's capacity to support life.

Environmental sustainability requires the maintenance of natural capital, which means that the consumption of renewable resources should not exceed the capacity of natural systems to replace them and that the speed at which we consume nonrenewable resources should not surpass the rhythm of substitution of lasting renewable resources. Environmental sustainability also means that the speed at which pollutants are emitted should not exceed the capability of the resources to absorb and process them.

SUSTAINABLE DEVELOPMENT

Economic and population growth, the availability and depletion of resources, and the absorbing capacity of the Earth and atmosphere are at the core of discussions and concerns about sustainable development. Concerns about sustainable development have a long history, starting with Thomas Malthus, but the use of the term *sustainable development* is of fairly recent origin. The term found its use in the mainstream debate with the Brundtland Report, commissioned by the World Commission on Environment and Development (WCED), and was put on center stage during the United Nations Conference on Environment and Development (UNCED; the Earth Summit), held in Rio de Janeiro in 1992. With the limits-to-growth debate, concerns about finite resources and the carrying capacity of the Earth ecosystem had become a main preoccupation, and computer projections of resource consumption established several critical parameters and demonstrated that human development (and survival on Earth) was ecologically constrained. In other words, the carrying capacity is finite. This entry examines the implications of the Earth Summit and the ongoing debate over the economic and cultural framework needed to achieve sustainable development.

Sustainable Development and the UN Debates

The Earth Summit was called to harmonize the many disparate paths of environmental protection that countries had pursued since the UN Conference on the Human Environment held in Stockholm in 1972, 25 years earlier. Many industrialized countries had incorporated environmental protection into their policymaking, but in the developing world, change had been much slower. Few developing countries had the capacity to respond to environmental threats, and still fewer had any inclination to build the capacity to do so. The major reason for this perceived discrepancy was that for the countries of the global South, environmental protection was inseparable from economic issues. Because of the persistence of severe poverty and perceived injustice in the

global South, environmental protection never attained the level of public concern that it did in the global North. This realization convinced the WCED (which issued the Brundtland Report) that it was futile to attempt to address environmental problems without a broader perspective that encompassed the factors underlying world poverty. When the WCED presented its report to the UN General Assembly in 1987, among its recommendations was a call for the UN to prepare a universal declaration and a convention on environmental protection and sustainable development. The official and stated purpose of the UNCED was to design strategies and measures to halt and reverse the effects of environmental degradation in the context of increased national and international efforts to promote sustainable and environmentally sound development in all countries. As a result, the mandate of the Earth Summit was extremely broad.

The WCED defined *sustainable development* as development that meets the needs of the present without compromising the ability of future generations to meet their own needs. The report called for cooperation between government and business and for the use of technology to address the pressing problems of balancing the social and economic needs of a growing world population with the requirements of a healthy ecosystem. The view prevailed that concerns about sustainability would stimulate society's efforts to become less resource intensive through the use of new technologies and to become more concerned about fulfilling human needs through global environmental management. The Commission was confident that human society would reverse the conflicts between economic growth and the environment, alleviate poverty, and lead the global community to greater cooperation between the global North and the global South.

The UNCED Earth Summit was perhaps the largest, and certainly the most publicized, gathering of heads of state and delegates from national governments, representatives of nongovernmental organizations (NGOs), journalists, youth groups, indigenous people, and other interested parties to discuss environmental and development issues. Maurice Strong—UNCED's Secretary-General—referred to the Earth Summit as a new beginning, but doubts remain about the sincerity

of the negotiating partners in trying to reach an agreement on major global environmental problems, which have since compounded in severity. Several treaties were signed and specific actions agreed to, but how effective the Earth Summit ultimately was remains an issue of debate.

Consensus was reached on the Rio Declaration and Agenda 21, and these agreements, along with the Framework Convention on Climate Change and the Convention on Biological Diversity, were adopted at the Earth Summit. Agenda 21 set out to formulate a blueprint for implementation of the other UN agencies' sector-specific activities regarding environment and development issues and to monitor progress on UNCED's agenda. To finance Agenda 21 and projects related to climate change/global warming and biodiversity, the World Bank's Global Environment Facility (GEF) was approached, and UNCED's Business Council for Sustainable Development—headed by Maurice Strong—was formed to advise UNCED on business issues and to stimulate involvement in specific actions. The developing countries' "Group of 77" wanted to establish an independent green fund in lieu of GEF, which it perceived as beholden to the interests of industrialized countries, the World Bank, and the corporate establishment; however, the idea was defeated by established interest groups from the global North.

Whose Common Future?

Within 1 year of the Earth Summit, the authors of the magazine the *Ecologist* published an edited volume that questioned the success and credibility of the UNCED Earth Summit. From their perspective, it was clear that the corporate sector was the dominant player both in the formulation of the various conventions and in the negotiations. Free market environmentalism was promoted—in their opinion—and corporate sponsors were given special access to the UN Secretariat. The desirability of economic growth, the market economy, and the Western development model were never questioned, and UNCED, thus, never had a chance to address the real problems of the environment and development relationship, according to these critics. The Earth Summit's action plan, Agenda 21, suggested ways to enable poor nations to achieve sustainable development

but never questioned the desirability of the rich nations pursuing the same. So the authors of the *Ecologist* asked the questions “In whose interest are we promoting sustainable development?” and “Who is managing it?” That the stage had been set for conflict between the global North and the global South was confirmed during later climate change negotiations under the UN Framework Convention on Climate Change (UNFCCC).

In a fundamental way, the Western development model is at odds with sustainability of the Earth resource base and carrying capacity, as it denies principles of equity that mandate equal access to resources and the “global commons.” The WCED called for justice toward the next generations but was unable to address the equity demands of the global South in the present time. The call from the developing countries for a more equitable share in wealth and resources was articulated in the Rio Declaration in terms of the “right to development.” At the Earth Summit, many leaders from the global South aligned with the global North in their advocacy of economic growth as the solution to global environmental problems. The prevailing view was that higher levels of economic development would lead to greater care of the environment and more efficient use of energy, thus resulting in lower pollution and greenhouse gas emission levels. Thus, the quest for justice was firmly wedded to the idea of development, and all parties could return to business as usual.

Growth Within Limits or Limits to Growth?

There are essentially two schools of thought on how to proceed toward a more sustainable development path. One—the UNCED approach—recognizes that change is necessary but believes in the power of existing institutions and economic forces to design new directives based on greater consideration for environmental and ecological concerns. Critics of this approach argue that a progrowth economic model must be replaced by an economic system that takes into account the limits of Earth’s ecosystem.

The UNCED’s Global Management Approach

From the UNCED perspective, some reforms and, in particular, new technologies are needed to

confront environmental threats and ecological needs, but no fundamental economic change is necessary. Based on concepts of green development and green technology, supporters of this approach believe that with the application of the right legal, policy, and management tools, nature’s resource base and its ecological services can be maintained and sustained. This approach reflects a commitment to economic growth and global expansion. Business-as-usual policies and proposed solutions are never questioned. As environment and development debates became more mainstream in the 1980s, attempts were made to mold environmental and ecological concerns into market-based models. Following the neoliberal trends in society, a search began for practical ways to incorporate sustainability into existing policies and planning approaches, which led to a whole new cadre of policy and business professionals working on sustainable development issues. The “greening of America” movement was the result. The UN’s warning that global warming threatened the upper and middle classes’ ski resorts in the Alps and the Rockies captured the headlines and brought out more support for climate change policies than any concern about poverty, floods, and food shortages in the developing countries.

Criticism of the UNCED Approach

It is this latter aspect that raised the question of sincerity and true commitment to UNCED’s sustainable development approach. One of the most outspoken critics of the sustainable development as global management approach has been Herman Daly. Daly questions the efficacy of progrowth economics in addressing global environmental problems. He also argues that if the marginal benefits of physical growth decline while marginal costs rise (as elementary economic theory would indicate), then there will be an intersection beyond which further growth would be uneconomical and unsustainable. The application of more advanced technology can (temporarily) expand production, but technological “progress” is usually accompanied by further resource depletion and pollution.

The economy is an open subsystem of Earth’s ecosystem, which is finite, nongrowing, and

materially closed. As the economic subsystem grows, it will incorporate an ever-greater proportion of the total ecosystem. Thus, economic growth is unsustainable, assuming that “natural capital,” or the sum of nature’s resources, is used up faster than it is being replenished. In effect, unsustainable development is intertwined with the loss of carrying capacity and limits to growth. The long-term result of unsustainable development is the inability to sustain human life, and such degradation on a global scale could lead to the extinction of humanity. Daly derides the concept of “sustainable growth” as an oxymoron and maintains that if we truly want to pursue sustainable development and if we value equity and fair share as human values, then the global North must make a commitment to use fewer resources and claim a smaller share of the global commons. It is for this reason that sustainable development has become a very laden political term in mainstream society. Critics of UN policies argue that it is hard to imagine that sustainability through improved environmental management would be achieved by means of greater integration of environmental reforms in the global economy even if the free market were to foster greater efficiency, higher productivity, and improved technology. Thus, the question “Is capitalism sustainable?” needs a serious answer.

Capitalism, Globalization, and Sustainable Development

Those who recognize the bipolar challenges of biophysical limits to growth on the one hand and business-as-usual approaches to development on the other argue that profound transformations of contemporary capitalism are needed sooner rather than later if we are to avoid dramatic disruptions of life on Earth. As the global economy is driven by the profit motive and foreign and corporate investment, and as we possibly approach the limits to growth, a less than equitable distribution of wealth and livelihood security has resulted. The implication of this is that sustainable development efforts require a restructuring of societal relationships, which has made discussions about sustainability and sustainable development highly politicized.

On this view of sustainable development, the Rio Conference has perpetuated a fixation on the

Western development model that fails to acknowledge ecological limits, and this has done a disservice to the global South, since equity concerns were never addressed. At the World Summit on Sustainable Development in Johannesburg in 2002, critics argued that it was time to move beyond Rio, to elevate development and equity concerns on the UN political agenda, and to focus more on the structural inequities in the global economy. This, critics argued, required that the Western development model be abandoned and that the rich reduce their “footprint” to ensure that the poor would be able to protect their livelihood rights.

Arguing that capitalism in its present form is unsustainable has become one of the major points of discussion among the critics of the impacts of globalization, including political ecologists, some of whom charge that sustainable development is an agenda of the global North designed to ensure the dominance of corporate elites. Environmental concerns associated with global production and foreign trade question the validity of the neoliberal economic agenda promoted by the United States, the World Trade Organization, the International Monetary Fund, and the World Bank. Since many negative effects of global production and foreign trade are not confined within national boundaries but spill over to affect other parts of the world (as, e.g., with greenhouse gas emissions) and since negative spillover effects are often more severe in developing countries than in the developed world, some environmentalists and ecologists argue that under the more open international trade regime, the economic growth model associated with capitalism should be abandoned. In its stead, we should pursue a sustainable development course that would promote fair-trade and fair-share principles.

Daly and others have argued that capitalist economic growth is about quantitative expansion and limitless transformation of natural capital into manufactured capital. Sustainable development, on the other hand, is about qualitative improvement in livelihoods, permitting increased economic activity only in so far as it does not exceed the capacity of the ecosystem. Thus, sustainable development requires an emphasis on physical parameters such as resources and carrying capacity, along with an acceptance that economic variables such

as income and profit will have to be adjusted accordingly. To many, it has become abundantly clear that the world's poor will bear the brunt of the damage to ecological systems and will carry most of the costs associated with it, while they are hardly to blame or in a position to make any changes themselves. New core values such as interdependence, empathy, equity, personal responsibility, and intergenerational justice will have to become the guiding principles and the basis for the transformation necessary to meet sustainability challenges.

An Equitable and Sustainable Climate Change Regime

To illustrate, greenhouse gas emissions reduction, necessary to achieve long-term stabilization of emissions concentrations in the atmosphere in order to avert climate change, will require a significantly lower carbon footprint of higher-income countries. If we consider that every person should have equal access to and share equal responsibility for the global atmospheric commons, and if we aim to achieve sustainable levels of greenhouse gas concentrations (450 parts per million) by the year 2050, as projected by the Intergovernmental Panel on Climate Change (IPCC), then we can assign specific carbon budgets for each country. The Stern Report projected the need for cuts of 80% or more in human-induced greenhouse gas emissions worldwide. Using the latest IPCC data, it is estimated that a safe level of emissions per person worldwide would be 2.0 tons of CO₂ (carbon dioxide) in 2050. Whereas most developing countries are currently well below a sustainable per capita limit, residents of the United States emit more than 20 tons of CO₂ per person per year, which means that substantial reductions will have to be made in the United States in order to reach both equitable and sustainable levels worldwide.

The implications of this are far-reaching, and it would seem that the longer we wait to implement the new energy systems, the more difficult it will be to achieve a sustainable level of emissions in an equitable way in the future. An equity- and sustainability-based policy response to global climate change would require that higher-income countries reduce their emissions to the greenhouse

gas stabilization level of 2.0 tons of CO₂ per capita at a rapid rate. Lower-income countries, in contrast, would be allowed to further expand their emissions until about 2040 and then cut back their CO₂ emissions to reach equity and sustainability levels at around 2050. As would seem clear from this example, it is hard to imagine that this can be accomplished under the business-as-usual UNCED approach.

SUSTAINABLE DEVELOPMENT ALTERNATIVES

The literature on sustainable development has long purported to focus on the tripartite relationship between economy, environment, and social justice. While all definitions of sustainability imply this trio of interrelated interests, only two are typically addressed in contemporary analysis: economic sustainability and environmental sustainability. This is true in conceptual and empirical analyses and policy practice. In conceptual terms, sustainability scholarship has focused primarily on normative accounts of sustainable development—the way it *should* be. Sustainability as a policy discourse and an embodied set of practices has yet to live up to its progressive potential to bring together these issues in a holistic way. In response to these forms of analysis, a new body of work on local and regional sustainability, with a more critical and empirical orientation, is emerging. The concepts of “alternative” sustainable development and “critical” sustainability studies sharpen their analytical foci on the relationship between conventional thinking and the “sustainability transition,” how sustainable development looks in practice, and what and who gets overlooked.

This entry has three sections. The first briefly introduces some conventional accounts of the sustainability literature and a critique of these perspectives. The second section summarizes the different perspectives from the critical sustainability studies standpoint. The final section seeks

to ground this point of view further by summarizing the linkages between sustainable development and environmental justice.

Sustaining the “Environment,” Sustaining the “System”?

Concerns for sustainable development made the international scene in the 1980s, when the Brundtland Commission, named after Gro Brundtland, the former Prime Minister of Norway, published its now famous definition of sustainable development. In the decades since, a variety of perspectives have emerged under the Brundtland mantle of sustainable development or have at least gained traction as a result of its popularity. Two key scales of intervention have been proposed by scholars and engaged in by policymakers—systemic and local engagement.

Systemic Intervention

At the systemic level, various perspectives have a key commonality worth noting. These perspectives share a belief in the power of the current economic system and faith in its intrinsic ability to regulate itself to produce progressive outcomes. These accounts are thus tinged with the neoclassical logic of “getting the markets right” and often conclude with appeals to a vague mix of moral imperatives, social conscience, and the threat of looming ecological disaster.

Specifically, these perspectives, which are exemplified by the work of environmental and ecological economists, economic futurists, and ecological modernists, focus on reformulating our current economic systems, especially in terms of redefining how the economic value of the environment is calculated. While these analyses are rigorous, especially those of environmental economists, and may even provide short-term fixes to environmental problems, they return to the same proposition as their neoclassical predecessors: that the market, properly defined, incentivized, and reflecting the real costs of development, is the most desirable institution for delivering human prosperity and ecological integrity. Here, market-produced values are surrogates for the value of “environment.” Wastewater treatment plants, for example, can account for the ecological services of a wetland by

calculating the cost of construction, maintenance, and human resource requirements. Thus, the economic value of a wetland is established by its ability to cleanse impurities from water. Market-oriented values also suggest that prices are triggered solely by signals from the system. Once growth surpasses replacement, for example, disincentives will trigger slower growth.

Ecological modernization theorists share this view, as its progenitors suggest that the ways in which societies value the environment are maturing and taking into account broader concerns than merely simple price triggers and costs. While these developments represent a breakthrough in valuing the environment in ways that traditional economists did not, the analysis falls short of engaging key questions such as the following: What “environment” is being saved? For whom? To what end? How do we measure a contested concept such as “nature’s” services? How do institutions work under conditions of economic change?

Local Engagement

Over the past few years, analyses that bridge the calls for developing a more sustainable society have been taken up by scholars who focus their analyses on the roles of individuals, nongovernmental organizations, and institutions in shaping more sustainable outcomes. In particular, these scholars have not focused on how existing systems can be overhauled to support economic growth per se, nor have they kept an overly narrow focus on the “environment.” These scholars have also called into question the societal implications of sustainable development goals and policies.

Critical Sustainability Studies

Critical commentaries on sustainable development have begun to ask some of the crucial questions raised above. Debates rage on the capacity of local authorities to act in the service of sustainability and the meaning and usefulness of the concept itself. For some, many of the environmental benefits of urban sustainability initiatives accrue to middle-class communities, often at the expense of peripheral local sites as well as those far away. Others have commented on the discursive nature of sustainability. In sustainable

development, there is a central storyline for policy discourses such as ecological modernization. This notion of a “storyline” suggests that sustainable development can be read as a new power/knowledge discourse for organizations seeking to accumulate power. Do the values and institutions of sustainability prioritize the value of capital and the maintenance of existing patterns of social relations? Or can sustainability discourses offer a counterhegemonic opportunity for subaltern groups to reshape urban environments, making them more equitable? Are there complementarities between those actors who focus on social reproduction and sustainability discourses—rather than those solely with environmental concerns—to produce outcomes that have a “red-green” tinge?

Subaltern Sustainability

Scholars are now applying the concept of environmental justice to sustainability practice to reveal that equity and justice are largely divorced from sustainability initiatives. Instead, these authors argue, sustainability is really focused on environmental protection or sustained economic development. They also argue that to be environmentally sustainable, cities must also be socially sustainable. Indeed, a sustainable society is one that looks to issues of social inclusion and welfare, along with economic opportunity and a green environment. The terms *just sustainability*, *actually existing sustainabilities*, and *subaltern sustainability* were coined as an explicit attempt to link issues of social equity to economic and environmental sustainability policy and practice. These concepts are important in critical sustainability theory. By bringing together the sustainability literature and the environmental justice literature, scholars have sought to create a vocabulary for political opportunity and mobilization, both in local government and in the grassroots. Indeed, there remains a critical need to examine how sustainability might be “mapped” onto the current geography of neoliberal capitalism and, more important, where the opportunities for broader, more inclusive political engagement with sustainability might present themselves.

SUSTAINABLE FISHERIES

Until well into the 20th century, ocean resources were believed to be infinite. The “freedom of the seas” paradigm that existed from the 1800s was largely informed by Hugo Grotius, the 17th-century natural rights writer, who argued that the oceans’ resources were inexhaustible and that fishing regulation was unnecessary. However, more modern scientific reports represent a very different state of affairs, making apocalyptic predictions about the state of the planet’s fish stocks. The most alarming forecasts claim that the stocks of all commercial fish and seafood species could collapse by the middle of the 21st century if present trends continue. Indeed, fears have reached such epic proportions that many commentators argue that the current international fisheries situation amounts to a crisis, second only to global warming in significance. Although such forecasts are typically contested by the world’s fishing

industries, there is little doubt that many fish stocks around the world are well below their “maximum sustainable yield”—that is, the largest catch that can be taken continuously from a stock so that it does not deplete it irreparably. This entry reviews the status of fish stocks today and explores the causes of, as well as various government responses to, the problem on national and international levels.

Collapsing Fisheries

A worldwide increase in “fishing effort” (the amount of fishing) since the late 20th century has corresponded with declining stocks and smaller catches. The total fall in global catch between 1994 and 2003 has been estimated at 13%. The explanation most frequently offered for this decline is that there are now too many boats chasing too few fish. Between 1970 and 1990, the Food and Agriculture Organization of the United Nations (FAO) recorded a doubling in the world fishing fleet to more than 1 million large vessels and 3 million smaller boats. Not only are there now more boats at sea, but each of these is likely to be more successful than ever before at catching fish. Fishing underwent vast technological changes over the 20th century, a process known as “technical creep.” The so-called overfishing crisis has its roots in the turn of the 20th century, which saw the capitalization and mechanization of fishing fleets and the widespread use of steam trawlers in the Atlantic. For instance, these technological developments resulted in the collapse of the Great North Whale Fishery in 1880 and the once booming herring and tuna fisheries in the Atlantic in the early part of the 20th century. Despite such crashes, advancements in catching technology continued. Fishing gear such as nets and modern equipment such as sonar and geographic information systems are being constantly improved so that each vessel can catch many more fish than ever before in a single trip.

As a result of this continuous increase in fishing activity, the United Nations (UN) states that 52% of the world’s commercial fish species are fully exploited, 17% are overexploited, and 8% are depleted. And according to the International Council for the Exploration of the Sea, slow-growing and therefore vulnerable deep sea fish,

such as orange roughy, are roughly 90% less numerous than they were in the early 1970s.

These alarming global statistics take on even more significance when considered with respect to particular geographical regions. For example, the collapse of the once abundant Grand Banks cod fishery in Canada in the early 1990s has become emblematic, and many people are familiar with the contemporary decline of the North Sea cod. This has caused widespread concern as the numbers of these fish are well below what is considered sustainable. Europe's fisheries scientists now estimate that cod spawning stock in the North Sea—that is, the section of the population responsible for reproducing—has declined by more than 80% since the early 1970s, and many are concerned that it could follow the Canadian example if radical action is not taken. But such problems are not confined to the Western world. For instance, some tuna stocks in the Pacific have been reduced to 15% of what they once were, and the economically important Patagonian toothfish fisheries in the Southern Pacific Ocean are also considered vulnerable to stock collapse. Similar stories can be told about almost every ocean.

Sustainable management of fish stocks is crucial because as fisheries are an extractive resource, fishing practices such as trawling can harm marine environments more generally. Moreover, these reports of unsustainable fisheries are even more disturbing if seen in the light of the rapidly increasing global demand for fish, which has doubled in less than 30 years, according to the FAO. Fish and seafood provide an important source of nutrition for both humans and animals (in the form of fishmeal, which is often harvested unsustainably), and they provide important employment. The collapse of the Grand Banks fishery, for example, cost that region more than 40,000 jobs. Fishing directly or indirectly sustains the welfare of many coastal regions around the world. However, the dependence on fisheries and related industries varies from country to country. In the United Kingdom, the fishing industry makes up less than 0.5% of gross domestic product, a figure less than the British lawnmower business. But dependence on fishing increases to 10% on the Atlantic coast of Spain and around the shores of Scotland. So while the number of jobs in the fisheries sector represents a low percentage of *overall*

employment in many countries, their socioeconomic importance is still huge.

A “Tragedy of the Commons” and Government Responses

Given that fisheries are so crucial to us as a source of food and means of employment, it is perhaps surprising that we are still facing major problems with their sustainability. One of the reasons for this can be explained with reference to the “tragedy of the commons,” in which the rational, self-interested acts of individuals destroy a common good. This allegory, developed by Garrett Hardin in 1968, is probably the most enduring explanation for resource overexploitation. Many natural resource commentators have used this allegory to exemplify the dilemmas involved in fisheries management. Fisheries are often described as “common-pool resources,” which, because of their nature, are difficult to divide up or fence in. Hence, what one user of the resource does can affect what is available to another user. This situation may lead to a scenario where resource exploitation happens in a way that neglects broader social-environmental responsibilities. The allegory shows how environmental or social externalities arise because self-interest drives economically rational actors to maximize their individual profit, since in a commons, the costs of doing so are shared by all yet the benefits accrue fully to the individual. The ultimate result is resource *overexploitation*, where everyone loses.

With respect to the world's common fisheries, the “external cost” relates to the fact that an individual fisherman's unrestrained profit maximization can damage the sustainability of fish stocks, thus making it harder for other fishermen to catch fish today and in the future. Essentially, it is the “common property” condition of ocean resources that has been blamed for overfishing.

European Union Policy

This conundrum of open access to common fishing grounds affected most 19th- and 20th-century fisheries, and many observers maintained that its solution was beyond the scope of single nation-states acting alone. One of the most notable multilateral solutions to overfishing is the

European Union's (EU's) Common Fisheries Policy. Although fisheries policy in the EU dates back to the early 1970s, the Common Fisheries Policy was not ratified by the member states until 1983. It was designed to give Europe's fishermen equal access to the resources of the EU's "common pond" and to ensure the "economically rational" use of fisheries within the context of a series of social and, later, environmental objectives. That is, the primary purpose of this policy is to ensure the sustainable exploitation of Europe's fisheries.

Notwithstanding this commitment to the goal of sustainable development, stresses remain between the policy's environmental, economic, and social objectives. For instance, tensions still exist between the need to protect vulnerable stocks such as the North Sea cod for environmental reasons and the fishing industry's requirement to make a living and support coastal communities. Indeed, it is generally believed that the Common Fisheries Policy may have compounded the problem of unsustainable fisheries in Europe. Under it, for example, the *limits* on the amounts of fish that fishermen can legally land in a specific time period (fish "quotas") are said to promote *overfishing*, through a practice known as "high grading." This means discarding from the catch "substandard," or unsellable, fish to increase the proportion of valuable fish in the allocated quota. Often, fishermen cannot bring themselves to throw back the already dead fish and so may land them illegally. These fish, caught and landed outside quota limits, are known as "black fish."

Overfishing in the EU has also been blamed on lax enforcement of existing regulations, fishermen's reluctance to comply with them, and the failure of politicians to follow scientific advice on stocks and put in place the measures needed to secure sustainability. But overfishing problems are not confined to Europe. Through access agreements, the EU has actively encouraged deployment of its excess fishing capacity to Africa, South America, and the Indian Ocean. Nongovernmental environment and development organizations have voiced concerns about this export of resource overexploitation to developing countries, arguing that access agreements represent a form of neocolonialism.

For some commentators, the solution to the tragedy of the commons is privatization of

resources that were once open access. As the allegory demonstrates, it appears to be the disjuncture between the universal right of entry to a fishery and the lack of individual responsibility for its overall maintenance that creates the incentive to overfish. Therefore, these commentators argue, externalization of the costs of exploitation onto the whole community of commons users can be remedied by establishing private property rights over the commons. Such rights encourage the internalization of externalities, because if you are legally identified as the owner of the resource (so the argument goes), then you will be more likely to look after it.

Individual Transferable Quotas

Privatizing ocean resources may not be an attractive solution, so long as they are regarded as what the UN calls the "common heritage of mankind." What is more, even if using property rights as a management method were theoretically sound, enforcing them on *mobile* resources might be problematic, for it is not yet feasible to fence off migratory fish species, such as herring or tuna. Consequently, it is only possible to apply a manner of privatization in the form of "individual transferable quotas," or ITQs. These are shares of fishing effort allocated to individual fishers, who can either use that effort themselves or sell it to someone else. ITQs thus approximate a privatized situation, providing the conditions for a market to operate. They are used in Iceland, New Zealand, and elsewhere and have had some success. They are said to afford greater flexibility than standard quotas because fishermen can sell them in hard times, or purchase quotas for valuable fish they could not otherwise land legally, instead of discarding them overboard.

Despite its attractions, there are several significant limitations to this system. For example, ITQs have in some circumstances led to "buyouts" whereby economically thriving operators buy quotas from smaller or less successful fishermen, and as a result, some coastal communities have eventually been altogether deprived of their fishing industries. Hence, the system may not be socially sustainable. What is more, this system does not entirely solve the problem of high grading, and so it is not fully environmentally sustainable either.

International Policy Responses

As well as the quasi privatization of fish resources, some policies have privatized the sea itself. Although much of the ocean is still part of the global commons, some of it is now “territorialized,” or, in effect, privatized, by nation-states. The conditions for this were created by the UN Convention on the Law of the Sea of 1982, which provides the overall legal framework for all ocean activities and establishes general obligations for safeguarding the marine environment. Its key provision is the establishment and extension of exclusive economic zones, or EEZs. These zones allow nations to have territorial and exploitation rights up to 200 nautical miles from the shore, covering all natural resources.

The international fisheries governance regime, however, may fall short. First, coastal countries are not obligated to responsibly manage their fisheries within their EEZs. Second, problems arise when some countries do not wish to collaborate or cannot reach agreement, as there are no binding laws on resolving disputes over resources. Also, introducing EEZs has actually encouraged governments to expand their fleets, thus stimulating overfishing. Yet, paradoxically, the expansion of territorial limits partly stemmed from an “overfishing” crisis in the internationally shared territory beyond them: the “high seas”—a global commons where open-access conditions prevailed and where there was a regulatory free-for-all. Today, the high seas are managed by the UN’s Regional Fisheries Management Organisations. However, they are largely ineffective, principally because they have no means to exclude vessels not abiding by their rules.

International fisheries governance is a mish-mash of codes of conduct and frameworks. Global commitments to sustainable fisheries include the UN’s Convention on Biological Diversity (Article 14) with its Action Plan for Fisheries (1992) and the UN Agreement on Straddling Fish Stocks and Highly Migratory Fish Stocks (Article 12, 1995). The most far-reaching is the nonbinding FAO Code of Conduct for Responsible Fisheries (1995). The code explicitly demands participative and transparent decision making by countries and regions. It also calls for “efficiency and effectiveness” to achieve “timely solutions.” At the United

Nations Conference on Environment and Development (the Rio Conference, or Earth Summit) in 1992, countries agreed to ensure “rational and sustainable” fishing. This commitment was reinforced and elaborated at the World Summit on Sustainable Development in Johannesburg in 2002, where it was decided that fish stocks should be maintained or restored by 2015. Given all these codes, it is easy to see why fisheries policy is an expanding area for governance.

One set of mechanisms that is fast gaining purchase in the search for sustainable fisheries consists of market-based instruments targeted to consumers. Eco-labeling and green consumerism now form part of a dominant discourse that might go some way toward eliminating unsustainable fishing practices. Consumer pressure sometimes forces retailers, keen to appear “green,” to source from fisheries certified as “sustainable,” and this encourages fishermen to move to healthier grounds or to use “friendlier” fishing gear. However, as in the ITQ example above, these market mechanisms may be inadequate to achieve and maintain maximum sustainable yield. Among other problems, they rely on consumers having sophisticated information about complex ecological processes and on their being prepared to exercise their spending powers. Second, although eco-labels may tell us that a fishery is “sustainable,” it may not tell us how many miles the fish has travelled in its journey from the ocean to the supermarket shelf and how much atmospheric carbon this has contributed to climate change.

SUSTAINABLE FORESTRY

According to the Food and Agriculture Organization of the United Nations (FAO), *sustainable forestry* may be defined as

the stewardship and use of forests and forestlands in a way, and at a rate, that maintains their biodiversity, productivity, regeneration capacity, vitality, and their potential to fulfill, now and in the future, relevant ecological, economic, and social functions, at local, national, and global levels, and that does not cause damage to other ecosystems. (UN Forum on Forests, n.d.)

There are four general goals of sustainable forest management (SFM): (1) to ensure a continuous supply of timber; (2) to ensure local populations' access to a wide range of nontimber forest products; (3) to conserve natural forests for biodiversity, habitat, amenities, and ecosystem services; and (4) to sequester atmospheric carbon in support of climate change remediation. Strategies for pursuing SFM typically make the following assumptions:

- Forests will continue to regenerate naturally over the long term (more than one human generation).
- Forest resource stakeholders (from local communities to transnational timber companies) have sufficient technical knowledge, institutional capacity, and self-interest to manage natural forests for the long term.
- A clear policy framework for SFM exists that is consistent at various intergovernmental levels.
- A politically accountable public entity exists, with the capacity to effectively identify various forest resource stakeholders and consistently monitor their behavior over time.
- Market demand for products and access to markets are relatively stable over the long term.
- Forestland tenure (i.e., property ownership) is clearly delineated, and viable judiciary and police capabilities exist to justly enforce legitimate individual and collective property ownership rights to forest lands.

Despite regional variations, three common themes have emerged among the guidelines for SFM that distinguish it from its predecessor,

sustained yield management: (1) a shift toward a more holistic perspective by changing the unit of analysis from the individual natural resource (e.g., timber or wildlife) to the larger ecosystem with which the resource is entwined; (2) a broadening of scope, from the economics and biology of renewable resource extraction to the social and cultural contexts in which such activities occur; and (3) an expansion in the range of benefits (products and services) provided, from timber for industrial wood production to timber and numerous different nontimber forest products and ecosystem services (carbon sequestration, soil and watershed protection) that SFM claims to provide.

Global Extent of Sustainably Managed Natural Forests

According to the FAO, approximately 30% of Earth's land cover (4 billion ha [hectares]) is forested. From 1990 to 2000, 8.9 million ha of forestland was lost annually to deforestation. In the 21st century, this rate has decreased to 7.3 million ha per year. A global estimate of how much of the remaining forestland is sustainably managed is difficult to determine. More than 200 million ha is currently certified as being sustainably managed by the Programme for the Endorsement of Forest Certification Schemes (PEFC). There are also large areas of land enrolled in programs that promote SFM that are not certified by the PEFC. For example, 440 million ha (11% of the world's total forest cover) is under some form of community-based ownership, and another 12% to 15% of the world's natural forests are managed by timber concession agreements. Another 12% of the world's forests (468 million ha) are in designated protected areas. Therefore, approximately 35% to 37% of the world's forestlands are being managed in some fashion. It is important to note, however, that not all community forests, forests under timber concessions, or protected forests are managed sustainably.

The Montreal Process

The ecological dimensions of SFM are predicated on the first five criteria for SFM, as endorsed by the Montreal Process of 2003, one of nine working groups established to develop SFM guidelines.

The Montreal Process criteria are discussed below because the countries involved in the process account for the majority of the world's forests.

Creation and Maintenance of Biological Diversity.

Ecological research demonstrates that diverse ecosystems are resilient ecosystems. A forest with a wide array of species is less susceptible to potentially catastrophic disturbances such as insect and disease outbreaks, wildfires, and major storm events than a forest with relatively fewer species. Biological diversity is measured in terms of habitat, species, and genetic composition. SFM seeks to create and maintain biodiversity by focusing on management at the landscape level rather than at smaller scales (such as an individual forest).

Forest Health. Maintaining forest health through SFM is essential to ensure that basic ecosystem processes operate within their historic ranges of variation (in terms of frequency, intensity, and scale). Health can be assessed by evaluating the area of forest affected by insects, disease, competition from exotic species, fire, storm, land clearance, permanent flooding, salinization, and domestic animals occurring above and beyond the historic range of variation. Additionally, changes in fundamental ecological processes, such as nutrient cycling and pollination, can affect forest health.

Ecosystem Services. Healthy forests contribute to the protection of adjoining ecosystems, especially the soil and water regimes of those areas, and thereby provide useful environmental services within the larger landscape. Healthy forests act as buffers against soil erosion from both runoff and wind and as a filter, removing pollutants from water before they reach groundwater supplies and streams. Reductions in soil erosion result in less sedimentation in streams and rivers. Additionally, forests help provide clean air by filtering pollutants such as ash, pollen, and smoke in Earth's troposphere.

Forests can also have a significant effect on climate. At the local level, trees provide shade and absorb heat energy, resulting in a cooling effect on both land and water. In the winter, trees can act as a windbreak and can moderate soil temperatures.

And at both local and global levels, forests play an important role in the carbon cycle.

Role of Carbon

Forests are both carbon sources and carbon sinks. A forest is a source when the amount of carbon released through respiration, decomposition, and burning exceeds the amount of carbon taken up (sequestered) through photosynthesis. Conservatively, deforestation and unsustainable forest management account for about one sixth of global carbon dioxide (CO₂) emissions.

A forest is a sink when the amount of carbon sequestered exceeds the amount of carbon released. A global estimate of the total carbon stored annually in forest biomass is 283 Gt (gigatons; 1 Gt = 1,000,000,000 tons). Well-managed forests have the potential to absorb about 10% of global carbon emissions into their biomass and soils. Additionally, solid wood products, such as building materials and furniture, provide long-term carbon storage.

Currently, incentive-based carbon markets are emerging to encourage landowners to engage in forest management practices that increase carbon uptake and storage. Market-based cap-and-trade mechanisms for reducing CO₂ emissions (similar to that currently in place in the United States for sulfur dioxide) would likely have important implications for SFM.

Forest Productivity

Traditionally, forest productivity was measured in direct relation to timber production (i.e., the production of forest land area, the volume of growing stock, the area of planted vs. naturally regenerated forests, and the annual removal of timber products vs. the amount of annual growth). While these indicators are still important, the definition of forest productivity has expanded to include other measures, such as biodiversity, the economic values of nontimber forest products, and ecosystem services.

Forest management practices can have significant impacts on productivity (both positive and negative). Choosing species well suited to a particular area, incorporating genetic improvements such as disease resistance and rapid growth, and

applying management tools (such as prescribed fire, thinning, and control of exotic invasive species) can increase both traditional and nontraditional measures of forest productivity. Other factors that affect productivity include forest species composition, temperature, rainfall, and soil depth and nutrient content.

Social Dimensions

Sustainable forest management explicitly recognizes the importance of the human and social dimensions of forest management, more so than conventional notions of sustained yield harvesting. The emerging interest in the human dimensions and social aspects of forest management correspond with a growing awareness of the significant contribution of deforestation to biodiversity reduction, climate change, and watershed degradation in low-income countries of the global South. As much as 30% of tropical deforestation is caused by small-scale, resource-poor cultivators, many of whom have been economically marginalized by large-scale, Western-style development projects. Accordingly, many proponents of SFM have argued for the inclusion of local communities into SFM programs. These have taken several forms (including biosphere reserves, integrated conservation and development projects, extractive reserves, social forestry, and community forestry), the objectives of which are the following:

- To protect agricultural land from soil and wind erosion, water pollution, and other adverse environmental conditions, thereby improving environmental quality
- To increase the supply of fuelwood, basic construction materials, and nontimber forest products, typically for noncommercial household consumption, thereby improving the quality of life at the household level
- To enhance the natural beauty of the landscape for passive recreational activities
- To provide employment for unskilled rural workers

Challenges in Sustainable Forest Management

Ecologically, the inadvertent and unintentional introduction of exotic invasive species is probably

the most serious challenge to the health and integrity of almost any ecosystem today and also to SFM. Exotic invasive species typically have a negative impact on biodiversity by displacing native species and altering ecosystem functions (e.g., changing the fire regime, nutrient cycling, or hydrology). Genetic biodiversity can also be corrupted as exotics hybridize with native species, altering the native gene pool. Worldwide, upward of 80% of endangered species could suffer losses due to exotic invasives, at a cost of \$1.4 trillion.

Other ecological challenges include soil conservation (minimizing erosion and compaction), water quality and quantity, and wildfires. Policies that encourage the identification and removal of invasion pathways and support public education for recognition and eradication of exotics are needed to fight this particular battle. Forest management practices that minimize soil damage and protect waterways are also needed.

Economic Challenges

The expansion of traditional forest management, based on the principle of maximum sustained yield of a single forest product such as timber, to management for multiple products, environmental services, and cultural values poses troublesome challenges to conventional neoclassical resource economics, with its focus on utility-maximizing, self-interested, rational economic actors operating in a free market context. Most equilibrium models of sustained-yield timber management presume concave utility and production functions, resulting in a single equilibrium point indicating the level of maximum sustainable harvest during a specific production cycle.

In the multiproduct, multiuse definition of SFM, however, where there are many production functions, there will be multiple equilibria, each of which may be affected by different rates of biological reproduction for different species, by their varying degrees of resilience to disturbance, and by the resource use behaviors of various forest stakeholders. Add to this the additional layer of complexity associated with the multiple institutional contexts in which different forest stakeholders operate, and a market-driven model for SFM becomes problematic for effectively balancing the

economic wants of society with the ecological requirements of forests.

Social (Tenorial) Challenges

Land ownership and tenure patterns also pose challenges to SFM. Large forested areas around the world are increasingly being subdivided into smaller parcels as a result of various social processes (e.g., inheritance, in-migration, and household agricultural failure). Parcelization of property ownership often leads to forest fragmentation—the alteration of a continuous forest into isolated forest patches interspersed with land in other, nonforested uses.

From an SFM standpoint, applying traditional forest management practices to smaller parcels can be difficult, particularly when adjacent properties have conflicting uses. Additionally, these smaller parcels of forestland are subject to increasing levels of disturbance along their edges and may not be suitable for species that require interior forest habitat, even as the habitat for edge-adapted species is increased.

Policies that encourage connectivity between fragmented forests, maintenance of structural complexity in forests (i.e., multiple-age classes, snags, and coarse woody debris), and the adoption of varied management practices at multiple scales could offset the negative impacts of forest fragmentation.

Political Challenges

Sustainable forest management can be negatively affected by illegal activities, such as trespassing, timber theft, logging endangered species, and wildlife poaching. In major tropical timber-exporting countries, illegal logging accounts for more than 50% of total timber cutting. The World Bank estimates that illegal logging costs the developing world an estimated \$15 billion annually in lost assets and revenues, in addition to human rights violations and social conflicts. Additionally, up to 10 million ha are annually deforested or degraded as a result of illegal activities.

Other external threats to SFM, especially pertaining to protected areas, in the form of illegal land settlement by migrants and land

speculators pose significant political challenges for governments seeking to balance social problems (e.g., chronic landlessness) with forest conservation commitments. Many of these challenges could be addressed through effective political will and commitment to public policies that support the implementation of forest management plans and the enforcement of existing forestry laws.

Institutional Challenges

Sustainable forest management is also impeded by deficient institutional capacity. Where SFM is a national policy goal, governments often lack the institutional resources to effectively enforce policies that support SFM. At the community level, where SFM is often introduced by outside technical experts, it can be stymied by the lack of a preexisting communal land management tradition or by the domination of individual interests within the community, which may prevent the gains of SFM from being shared broadly.

Forest Concession Challenges

Worldwide, a minimum of 450 million to 500 million ha of natural forest is leased to private timber extraction and/or industrial wood-processing corporations under long-term forest concession agreements. Although the terms of such agreements may contain attributes of SFM (e.g., sustained yield management), many concessions, in practice, have been criticized by conservationists and economists for being overly destructive and economically wasteful, highly susceptible to corruption, harmful to local communities, and unsustainable over even the short term. Logging is believed to account for approximately one third of global deforestation, raising questions as to whether large-scale timber concessions can ever be sustainable.

Recent interest in community-based forest concessions for timber extraction has scaled down forest management areas from large industrial forest concessions (ranging from 50,000 to 25 million ha) to smaller (500–10,000 ha) production units, with strong local (community) participation and management interest in logging and marketing operations.

Innovations in Sustainable Forest Management

Conservation Concessions

Some conservation groups (e.g., Conservation International) have recently proposed to adapt the forest timber concession model to promote forest protection. In the adapted model, forest landowners (private, governmental, and customary) lease forests to investors (e.g., nongovernmental organizations) for a stable rent in exchange for maintaining the intact forest. The rental income from such concessions is allocated to local communities to offset their opportunity cost of income foregone in order to ensure forest conservation. In practice, the effectiveness of conservation concessions is often constrained by the inadequate concession enforcement capacity of forest owners, by questions of national sovereignty, and by external forces over which local concession holders have little control.

Sustainable Urban Forestry (SUF)

As defined by the Sustainable Urban Forests Coalition (SUFC), urban forests are “the aggregate of all vegetation and green spaces that provide a myriad of environmental, health and economic benefits for a community.” Sustainable urban forestry is defined as “the art, science and technology of managing trees, forests and natural systems in and around cities, suburbs and towns for the health and well-being of all people.” Recognizing the positive public health and local watershed and climate benefits of maintaining forests in an urban landscape, several municipalities in the United States and elsewhere have initiated urban forest management plans as part of active land stewardship programs.

Reduced-Impact Logging (RIL)

Reduced-impact logging is the application of scientific and engineering knowledge and techniques, in conjunction with education and training, to improve operating methods for harvesting of industrial timber so as to minimize collateral damage to the residual forest and other elements of the forest ecosystem during a harvesting operation.

Forest Certification

Forest certification is a voluntary process in which a third party evaluates and certifies the management of a forest against a particular set of sustainability standards. Although applied mainly to timber extraction, certification also can be applied to the management of nontimber forest products.

Secondary Forest Management

Forested areas that have regrown through natural regeneration after a major disturbance (e.g., clear-cutting, fire, timber harvest, and/or insect infestation) over time such that the effects of the disturbance are no longer evident are commonly called “secondary forests.” As human pressures reduce the global area in natural forests, the sustainable management of tropical secondary forests will become an increasingly important component of SFM.

Conclusion

The attributes of forests around the globe, and the social and political challenges that shape them, vary widely. As a result, there is no one prescription for SFM for all forest types. Management activities must first be tailored to address the specific needs and challenges of forests at the local level. These local-level management practices must then be integrated at regional, national, and international levels. This is not an easy task. But the continued efforts of the nine international working groups to formulate measurable guidelines for SFM demonstrate a global interest in enhancing forest management strategies and ensuring sustainability of forest resources for future generations.

SUSTAINABLE PRODUCTION

Sustainable production is the process of creating goods and services that are both environmentally and socially responsible in addition to being economically successful. The geographical effects of sustainable production are ubiquitous, from the transport of goods and the location of facilities to the effects of industry on people and the environment. The motivation for sustainable production, approaches to implementation, frameworks for consideration, and ongoing efforts are all described in this entry.

Motivation for Sustainable Production

Environmental, economic, and social concerns have catalyzed the development of methods, tools,

and techniques for sustainable production. Industry-related environmental disasters, such as the deaths from the release of methyl isocyanate gas in Bhopal, India (1984), and the widespread publicity of the hole in the stratospheric ozone layer in the 1980s caused by ozone-depleting chemicals (e.g., chlorofluorocarbons, or CFCs) have spurred public outcry for better regulation of production practices and emissions. In response, international, regional, and national legislation has been enacted. The Montreal Protocol on Substances That Deplete the Ozone Layer (1987), adopted by many nations, bans the production and use of ozone-depleting chemicals. The 2002 European Union Waste Electrical and Electronic Equipment (WEEE) and the 2003 Restriction of Hazardous Substances (RoHS) directives place responsibility on producers to take actions that reduce environmental impacts. The 1990 U.S. Clean Air Act requires the U.S. Environmental Protection Agency to enforce limits on emissions from production facilities.

Additionally, the economic and social consequences of globalization have created a need for sustainable production. Increases in global competition have prompted the production of goods to move from industrialized to developing nations to avail of the benefits of lower labor costs and less regulation. This shift in industrial activities has changed global patterns of employment and production, with concerns raised about environmental impacts, labor practices, and worker health and safety. These concerns have inspired the development of economies and societies to improve quality of life. This inspiration evolved into the holistic concept of sustainable development.

Toward this aim, sustainability-oriented approaches have been adopted to reduce costs and improve manufacturing productivity and efficiency. The goal is to maintain manufacturing competitiveness while reducing the environmental impacts of production. Such approaches include cleaner production, pollution prevention, and just-in-time, lean, and environmentally responsible manufacturing. Adoption of these approaches by companies starts the institutionalization of sustainable production goals and practices.

Industry has sought to expand transparency and accountability for financial, social, and environmental policies and practices through the

adoption of standards and through communication about performance to stakeholders via sustainability reporting and product labeling. The International Organization for Standardization (ISO) established environmental standards in 1996 (ISO 14000) to complement the existent quality standards of ISO 9000 (1987). The Global Reporting Initiative guidelines (1997) established a systematic way for companies to report sustainability performance that is audited and scored for transparency and credibility. The Social Accountability International (SAI) SA8000 standard (1997) measures corporate performance in protecting workers' rights. AccountAbility's A1000 standards (1999) report on corporate social and ethical performance. Many companies communicate environmental and social responsibility through product labeling about environmental, fair trade, and child labor-free practices.

Sustainable Production of Goods and Services

Sustainable production strives to increase processing efficiency, eliminate waste, and create benign outputs. Increase in processing efficiency is achieved by reducing the use of materials, energy, storage, labor, and time while improving product quality and reducing process variation. Microlevel and macrolevel process planning strategies form the backbone of pollution prevention or cleaner production efforts by improving operational parameters and process flows. The Toyota Production System improves quality by eliminating inefficiencies (*muda*), overloading of equipment or people (*muri*), and variation in processes and products (*mura*). Under a just-in-time manufacturing approach, production is output pulled instead of input pushed—that is, production occurs when demands for products arise rather than when supplies for production are available. A just-in-time philosophy necessitates fast distribution of inputs across the supply chain once a demand is recognized. Lean manufacturing concepts have grown out of these approaches, which started to be widely adopted in the 1980s. Lean manufacturing has a similar goal of eliminating waste by ensuring that each production activity creates the value the customer demands; the catch phrase “lean and green” has emerged to capture this connection.

Eliminating Waste

Quality engineering methods reduce waste by decreasing the number of defective products through continuous improvement efforts such as Statistical Process Control. Guidelines such as design for assembly eliminate waste by reducing labor and the time needed for assembly through optimization of object handling. The concept of eliminating waste is derived from process efficiency efforts but involves thinking beyond traditional processing concerns. Extending the usable life of process consumables can directly eliminate waste, as, for example, in cleaning and reusing metal-cutting fluids. Similarly, finding uses for by-products of processes (often unintentional outputs) eliminates waste while creating market opportunities. Industrial ecology and cradle-to-cradle approaches, developed in the 1990s, seek to establish an ecosystem-like view of production systems, where outputs become inputs to secondary production operations. For example, the eco-industrial park in Kalundborg, Denmark, started sharing waste steam and other by-products between an electric power generator, product manufacturers, and the local community in the 1970s.

Creating Benign Outputs

Sustainable production encourages the creation of benign rather than detrimental outputs for environmental and human health. Green Chemistry, developed in the 1990s, innovated processing alternatives that reduce toxic chemical inputs, outputs, and by-products. Substituting hazardous inputs with more benign, reclaimed, renewable, recycled, or recyclable materials promotes sustainability and can be aided by Design for Environment (DfE), which evolved in the 1990s. Energy efficiency efforts reduce emissions along with using renewable energy; for example, wind turbines power the Ecover factory in Belgium, which makes environmentally friendly cleaning products. Some companies purchase renewable energy credits (RECs) or carbon offsets to offset emissions.

Frameworks of Sustainable Production

The efforts described above mainly affect production processes, but production involves much

Figure 1 Material and energy flows in a simplified supply chain

Source: Authors.

more than manufacturing. Through the lens of sustainability, production can be viewed as a supply, value, or commodity chain that includes many actors and flows of resources. A life cycle view of production aids the formulation and implementation of policies and practices based on geographical, demographical, and sustainability concerns.

Supply Chains

A supply chain considers the relative location and capabilities of all stakeholders involved in the creation of a product. Typically, a supply chain is thought of as moving linearly forward between material processors, suppliers, manufacturers, distributors, retailers, and consumers. A supply chain may include reverse flows of discarded goods from consumers to collectors that take back, disassemble, and reuse the products. For sustainability, supply chains are considered as closed loops of material and energy flows through society and the environment that ultimately are conserved. Figure 1 depicts a simplified supply chain, where the arrows represent material and energy flows, which are labeled for reuse processes. No matter how processing for production or reuse rearranges materials and energy, by conservation laws, the

sum total of resources remains the same within society and the environment.

Value Chains

The value chain evaluates the remaining value of a product at different points in the supply chain. Product value may not correspond to ownership of the physical artifact but rather to its use, which has led to the development of services and product service systems to deliver value to consumers (e.g., auto leasing).

Commodity Chains

Commodity chain analysis studies the relationships between stakeholders and the steps involved in creating or delivering commodities (e.g., bananas) to consumers. The commodity chain evaluates social relations by financial transactions between actors, steps that increase commodity value, and methods of delivery. Analysis considers details such as commodity origin and destination; cost functions of steps; delivery by load, method, and supplier through particular hubs; regulation of commodities and transport; and value flows.

Life Cycle View

A product life cycle view considers all stages of product life, generally including materials extraction, production, manufacturing, use, and product recovery (or disposal). This final stage is also referred to as product end of life, end of use, or retirement. Product end of use and retirement convey the notion that products should be recovered to conserve materials within society and the environment, supporting sustainability goals. Life cycle assessment can be used to contrast the material and energy flows between products with comparable functions for all life cycle stages.

Each framework's view on material, energy, and monetary flows provides a unique approach to defining production, including a wider range of actors and steps than for processing alone. Additional sustainable production efforts address a wider range of stakeholders affected by production.

Sustainable Production Efforts Throughout the Supply Chain

Improving sustainability across the supply chain involves choices about supplier selection, logistics management, facility construction, and product end of life. Corporate social responsibility (CSR) encourages companies to work for the common good in terms of how products are made and sold and who profits. For example, Timberland, a footwear and apparel producer, established an annually assessed code of conduct for suppliers that requires fair treatment of workers and environmental performance improvement.

Logistics Management

Logistics management improves sustainability by reducing the need for and the impacts of transportation. "Going local" promotes procurement of materials, suppliers, labor, and products in the communities where businesses reside to keep economic flows within those areas and to reduce environmental impacts from transportation. Optimizing logistical networks can reduce transportation distances by locating operations near key supply chain partners (e.g., material processors, distribution hubs, or end consumers) or transporting goods in the largest loads possible. Choosing cleaner

transportation methods, as Peace Coffee, a fair-trade coffee roaster that delivers products to customers by bicycle and biodiesel-fueled vehicles, has done, reduces environmental impacts.

Facility Construction

Factories, warehouses, offices, and other supply chain buildings have impacts. Constructing new facilities on polluted sites, termed *brown-fields*, reduces the social and environmental impacts of production on communities and the environment. The U.S. Green Building Council created the Leadership in Energy and Environmental Design Green Building Rating System (or LEED standards) in 2000 to promote the use of environmentally friendly materials and energy efficiency in the construction, renovation, and operation of buildings.

Product End-of-Use Options

Much attention focuses on product end-of-use and reuse options, which add reverse flows to the supply chain and contribute to sustainable production. Product collectors recover retired products for reuse, repair, remanufacturing, or recycling. Remanufacturing inspects and repairs or replaces components to create a product of comparable quality with newly manufactured products. Recycling creates material inputs for production by separating, breaking down, and processing the materials embodied in discarded products. Discarded products that can be easily disassembled facilitate recovery and reuse. Design for disassembly guidelines assist in defining product structures that allow for nondestructive, efficient separation and reuse of product materials and components. Additionally, reverse logistics pose challenges for product reuse. Take-back systems, such as those in use in Germany, encounter difficulties in reaggregating products, dispersed to customers throughout markets, back to centralized locations. The burden of returning retired products is often placed on users, who may choose to store or discard the products, thus arresting the flow of energy and materials.

stand-ins for something, whether material (as in the case of places) or not (as in the case of the dove of peace or the Nazi swastika). Indeed, places are intrinsically symbolic, since places are, by their very nature, a part of space with meaning.

Geographers have long been interested in symbolic places and how symbols represent places. The Parthenon represented the birthplace of democracy in ancient Greece as, among U.S. citizens, the Liberty Bell may stand for independence from England. Paris and France may be symbolized by the Eiffel Tower, and St. Louis, Missouri, may be symbolized by its Arch. After the destruction of the World Trade Center, when New York City lost one of its significant symbols, an element in the debate about what would replace it involved the issue of whether to combine the symbolism of New York's dominance with memorialization of the victims of the terrorist attack.

Humans have imbued features of the natural as well as the built environment with symbolism. Ayers Rock in Australia, the San Francisco Peaks of Arizona, and Shaman's Rock in Baikal all have symbolic value to indigenous peoples, sometimes representing the domain of the gods or sacred space. The built environment of most cultures is replete with such sacred symbols—the medieval cathedral, the mosque, pilgrimage sites, and graveyards. Many countries are also imbued with symbols of the state, whether the mega blocks of Soviet communism or the Greco-Roman town hall of many small towns in the United States. Perhaps most pervasive in the newer built environments worldwide are symbols of the power of Mammon. As others have shown, the rich are more able to imprint their symbolism in places than are the poor.

The purposeful construction of buildings intended to be symbols has accelerated since the late 20th century; indeed, the millennium itself was intended to be symbolized in Britain by the eponymous Millennium Dome, a project characterized by cost overruns, delays, and rapid obsolescence. The Renaissance Center was built to symbolize Detroit's emergence from a dark age of urban distress. The world's tallest buildings, including Malaysia's Petronas Towers, Taipei's 101, the Burj Dubai in the United Arab Emirates, Shanghai's World Financial Center, and Seoul's International Business Center, symbolize

SYMBOLISM AND PLACE

Humans have always used symbols, and archeological evidence suggests that in nearly all societies, including prehistoric ones, particular places have held symbolic significance. Symbols are

When New York City lost one of its significant symbols, the World Trade Center, on September 11, 2001, an element in the debate about what would replace it involved the issue of combining the symbolism of New York's dominance with memorialization of the victims.

Source: Markus Seide/iStockphoto.

a never-ending race for superlative height and associated global status. The transformation of Bilbao from working industrial port to leisure destination is symbolized in Frank Gehry's Guggenheim Museum Bilbao, while each symbol of Dubai's conspicuous consumption outdoes its predecessors—from the Burj Arab to the Palm and World Islands. Sydney's Opera House arguably remains the only globally iconic symbol in Australia's built environment. Beijing's "bird's

nest" stadium reflected the aspiration that the 2008 Olympics would be a coming-out party for China as a global superpower. The list of recently built and future projects intended to "put a city on the world map" expands with each mega event and burst of capitalistic optimism.

But, of course, place has many scales, and everyday places are small, domestic, and imbued with meaning and symbolism. The word *place* derives from the Greek word *plateia*, meaning a square or courtyard surrounded by houses—hence, *piazza* and *plaza*. Places can range in size from a garden allotment with a symbolic scarecrow to a village with its green, a shanty town with legible (if transient) territorial markers, or a city replete with symbols (some copyrighted, such as New York's "I ♥ New York"), to countries (Egypt's pyramids) or perhaps even continents. These symbols are a form of shorthand. As examples of synecdoche, they stand in for the larger place of which they are a part. They may also represent a critical event in history (e.g., the Berlin Wall or civil rights monuments).

Symbolic places may be sites of continued strife and controversy, representing alternative interpretations of reality past and present, as in the case of Jerusalem.

Indeed, when symbolic places are consciously designed and constructed, as in the case of the memorial at the crash site of Flight 93 in Pennsylvania, it would probably be impossible to satisfy conflicting preferences. Symbolic representations in places where atrocities and tragedies have occurred, from Buchenwald to Belfast to Salem to Sebastopol, frequently have multiple and conflicting meanings or interpretations to both locals and visitors and to subgroups among them.

Ayers Rock in Australia is sacred to the Aboriginal people of the area.

Vernacular residential landscapes are encoded with conventional signs of social status and group membership legible to neighbors and outsiders. The landscape of privilege in high-income suburbs brims with the symbolism of class and exclusion. Lot size, architectural type, decorative detail, and even horticultural plantings symbolize the status of residents and broadcast messages of belonging or repulsion. Ethnic neighborhoods of American cities are usually easily recognizable by symbols even in the absence of their inhabitants. A Katrina-devastated small town in Louisiana may symbolize home and hope to some while simultaneously signaling governmental failure and global climate change to others. The symbolism of place is often in the eye of the beholder, as Dolores Hayden convincingly demonstrated, although she also rued the relative paucity of public memory in the urban landscape related to women and other marginalized groups.

Although some argue that symbols cannot be produced intentionally but rather are “organic,” in that they grow and decline as social meaning attaches to them, the contemporary marketing industry disagrees with that assumption, and certainly place marketing takes symbolism very seriously. Places lacking symbolic capital—that is,

that are absent from mental maps or are vague in the public psyche—must build or buy symbols that imprint in the minds of potential tourists, residents, and investors. Places unlucky enough to possess negative mental vibes must invest particular effort in metamorphosing their symbolic imagery. Slough, an industrial town west of London, was unlucky enough to be the target of a poet laureate (John Betjeman’s “Come Friendly Bombs and Fall on Slough”) in 1937 and is still defending itself against the slings and arrows of adverse publicity. Other locations, such as Tiananmen Square in Beijing, undergo refurbishment to fit the newly desired image. Places, of course, gain symbolic freight both from their material landscape and from the events that transpire in them. The government of China hoped that the Olympic celebrations of 2008 would subsume the events of 1989 in its most symbolic public space. But for most locations, changing the physical and/or psychic imagery to attract people and capital is a preoccupation that is generating a new profession—place marketing—and transforming (particularly urban) landscapes into places dressed to impress.

SYMPTOMS AND EFFECTS OF CLIMATE CHANGE

Long-term changes in the atmospheric concentration of greenhouse gases—notably carbon dioxide (CO₂), methane, and nitrous oxide—due to human activities has altered the radiative forcing of the atmosphere and its energy balance. The physical impacts of these disruptions, known collectively as climate change, are varied but present across the globe. Due to the central importance of the atmosphere in all global environmental cycles, the symptoms and effects of climate change are potentially present anywhere on Earth. Study of these issues requires practitioners to maintain a holistic view of global biogeochemical interactions. The primary feature of climate change effects, as increased energy is expressed in the

atmosphere, is less predictability and greater oscillations in environmental system behavior.

Air Temperatures

Globally measured surface temperatures have increased rapidly since 1979. Generally, the temperature increases are more severe at higher latitudes, as the atmosphere moves excess energy poleward. The warmest years in the instrumental record (extending back to 1850) are 2005, 2007, 1998, 2002, 2003, and 2006. However, temperature increases are not uniform, because of changes in atmospheric circulation and localized effects such as urbanization. These local processes are accounted for in global temperature change calculations and are not the cause of the documented global temperature increase.

Warming air leads to greater occurrence of heat waves; this trend is most pronounced in the polar regions (averaging twice the rate of lower latitudes) and becomes less evident toward the equator. Extreme high temperatures affect older or stressed organisms because the cardiovascular system must work so much harder to regulate temperature. While warmer winter temperatures have led to reduced death rates during the colder months, the increase in summer deaths far outweighs that reduction. These trends have been documented in human populations across the world and in multiple animal species as well. Warmer winter and nighttime average temperatures also mean decreased frost risk, changes in snowfall, and changes in the length of the growing season.

Ocean Changes

Global sea level has risen by more than 3 millimeters per year in the past decade, and it is uncertain if this rate will remain constant or increase. Sea-level rise is caused by oceanic thermal expansion and the melting of the world's ice caps and glaciers. As the majority of the world's surface is covered by water, warmer air temperatures are warming the ocean as well. However, due to the high heat capacity of water and the layered nature of the ocean, with little mixing of surface and deep water, ocean warming is a slow process that will occur over the next century-to-millennia time-frame. If temperatures stabilized today, the ocean

would continue warming for hundreds of years as deep-water mixing slowly occurs. Deep-ocean measurements have measured steady temperature increases throughout the world's ocean basins.

Warmer water is less dense than cold water, and thermal expansion of water has led to increasing sea-level rise. An increase in water temperature also lowers the ability of water to retain dissolved oxygen and carbon dioxide (CO_2), so that biological systems are stressed due to less oxygen for fish and other organisms and warm water releases even more CO_2 into the atmosphere. However, increased freshwater flow from melting glaciers in Greenland and other locations will lower ocean salinity in the high latitudes at areas of ocean multilevel mixing. Lower salinity allows water to absorb more CO_2 . This may be sufficient to offset CO_2 release from ocean warming in other areas but will lead to increased acidification of the oceans.

CO_2 reacts with water to form carbonic acid (used in carbonated beverages), which has a detrimental impact on calcium carbonate (sea shells) as it dissolves them and weakens their structure. Current models estimate pH being lowered to acid levels not seen for millions of years—which will have a catastrophic impact on corals and other calcium carbonate-shelled organisms. Changes in ocean circulation patterns could drastically alter the regional nature of these impacts.

While natural variability makes it difficult to determine trends, the intensity of tropical ocean storms—called hurricanes (Atlantic Ocean), typhoons (Pacific Ocean), and cyclones (Indian Ocean)—has increased, as measured by the Power Dissipation Index (PDI) in recent decades. The PDI is proportional to wind speed cubed and is highly correlated to temperature. While the number of tropical cyclones may or may not be increasing (this is difficult to determine due to the short record of data), the PDI is unequivocally increasing. The number of storms is less critical than the size of the storms because the nonlinear nature of storm damage (damage is correlated to the cubed power of wind speed) means that one severe storm may cause far more damage than several smaller storms put together. Increased El Niño activity has been posited by some studies, but results to date have been inconclusive. However, El Niño events disrupt hurricane formation

because of wind shear effects that do not allow hurricane vortices to form. A better understanding of El Niño and climate change effects is critically needed for long-term planning purposes.

Changes in the Hydrologic Cycle

As climate impacts are expressed throughout the system, changes will be most amplified by extreme events. Increases in moderate to heavy precipitation events in the midlatitudes are the best documented of recent changes. Evaporation and transpiration from plants is accelerated under warmer air temperatures and increasing atmospheric moisture content. Increases in atmospheric water vapor have been observed in recent decades, as every increase in atmospheric temperature of 1 degree Fahrenheit allows air to hold 4% more water vapor. A warming ocean combined with higher evapotranspiration leads to an accelerated hydrologic cycle. These factors interact to paradoxically create both increased drought and increased precipitation. Drought impacts are widespread, as the entire land surface heats and dries, while storm events are local-scale phenomena. Increased frequency of extreme daily rainfall has been documented and is coupled with an overall decline in the number of days with precipitation, so that there is heavier rainfall during a shorter period of time but more rarely than before. A major impact of increased continental drought is an increase in desertification—notably in the Sahel of Africa, in China, and in Australia.

Fires

Forest fires are affected by three major factors—fuel load, ignition agents, and weather. Climate change perturbations to natural systems increase fire risk in all three areas. Warmer temperatures mean longer growing seasons in boreal forests and more fuel production. Frequent storms lead to lightning ignition. Most important, climate change has caused increasing drought and hotter daytime temperatures, which correspond to more violent fires. Increases in fire frequency and extent have been documented in North America, Africa, and Australia. As fires increase in extent, they release the terrestrial stored carbon; this is a

positive feedback cycle, increasing the effects of climate change.

Ice Sheet and Glacier Impacts

The most visible impact of climate change has been changes in the Earth's cryosphere as ice melts globally under warmer temperature—especially in the polar regions. Greenland and Antarctica hold a substantial portion of the Earth's freshwater, and both of these areas have seen unprecedented changes in recent years. Decreases in the Greenland and West Antarctic ice sheets have been accelerating, and these two bodies of ice have sufficient stored-water volumes to raise the sea level by more than 10 m (meters) if both would melt completely. The East Antarctic ice sheet contains far more water and fortunately is currently stable. However, the dynamics of glacier retreat rates are not well understood, as conditions are changing in ways unprecedented in scientific history. A major uncertainty is how the meltwater below glaciers acts to speed their movements. Glacial speeds have dramatically increased in the past few years (especially in Greenland), and the recent Intergovernmental Panel on Climate Change (IPCC) assessment (AR4) noted that calculating future sea-level rise is speculative until these uncertainties can be better parameterized.

Globally, the vast majority of smaller glaciers are retreating, for example, in the high Himalayas, in the Andes, in Patagonia, and in Alaska. Mountain glaciers retreat has multiple additional impacts beyond sea-level rise. The impacts include increases in river volumes, more frequent flash floods, and increased risk of catastrophic floods from high-mountain glacial lakes. Once the upper-elevation glaciers have melted, there will be an increasing collapse in late-summer river volumes, as there is no more glacial melt available to supply rivers (and cities) in the dry season. River flows have also been measured to be peaking earlier in spring due to earlier snowmelt.

Sea ice extent in the Arctic decreases roughly 3% per decade, with higher shrinkage rates (about 7%) during summer, according to the IPCC AR4. This decrease is accelerating and is driven by a positive feedback mechanism that amplifies melting. The white surface of sea ice is highly reflective, and 80% to 90% of the sunlight reaching

the surface can be reflected without warming the system. This energy is thus lost. As sea ice retreats, dark blue water is exposed to sunlight. This dark water captures nearly all this energy, and the warmed water in turn melts more ice. Sea-ice extent and thickness have been decreasing at roughly 10% per decade since the 1970s.

The reduction in global ice volumes, however, is not universal. Ice volume is controlled both by loss due to melting or calving and by deposition from snow. A limited number of glaciers globally have increased in volume due to increased snowfall overwhelming the increased melting rates.

Biogeographical Impacts

Warming temperatures mean milder winters and earlier spring thaws. This results in a longer growing season and favors different plant species. Changes in phenology have been documented across the Earth, and 90% of these changes are consistent with temperature rise, including earlier spring blooming. These factors favor allergenic pollen-producing plants, and pollen counts have increased globally. Overall, it is estimated that Northern Hemisphere plants may rise 500 m or more in elevation and/or shift poleward more than 300 kilometers if dispersal corridors are available.

Cold winter temperatures are a major deterrent to insect population growth, and recent warming has increased the ranges of most insects, including mosquitoes and agricultural pest insects. Tropical infectious disease occurrence has exploded globally as human populations grow and temperatures warm. Disease occurrence is limited to regions where their vectors, such as mosquitoes or ticks, are able to thrive. *Anopheles* spp. and *Aedes aegypti* are two mosquito species responsible for the spread of malaria and other major tropical diseases. They have established temperature thresholds for survival, and the viruses/parasites within them have incubation periods that are also affected by temperature. As disease vector habitat increases because of warmer temperatures, diseases are expanding their range—especially in tropical highland areas that had previously provided refuges for populations from Papua New Guinea to Kenya. According to the World Health Organization, 30 new diseases have emerged worldwide since 1980.

Climate dictates the general range of vectors, while weather affects the timing and intensity of specific disease outbreaks. Climate change is creating more weather events that lead to longer and more sustained disease outbreaks. Moisture availability is also a limiting factor for vector survival, and the changes in the hydrologic cycle noted above have led to more frequent storm events, creating the stagnant water necessary for mosquito propagation.

Warmer winter temperatures are having a similar impact on agricultural and forest pest insects. Millions of acres of timber in Canada have been lost to beetle outbreaks due to the warm winters over the past decade. Agricultural fields have seen major shifts and increases in pest insects globally on account of less frost and fewer cold nights. This is a dynamic process that has had inadequate research, and so the long-term effects are not well understood. Based on reproductive rates, white flies, locusts, and aphids have been found to be especially responsive to rapid changes in weather and climate.

Overall, the IPCC AR4 report cites 29,000 observational data series that show change in environmental and biological systems. Nine out of 10 of these data show an increase in warming consistent with anthropogenic climate change.

Most of these data are from the higher latitudes and more industrialized countries. Further research in the tropics may yield additional symptoms and effects of climate change.

TAPHONOMY

Taphonomy is a multidisciplinary, multitasking body of knowledge that studies the processes affecting organic remains after death—that is, the transition of these remains from the biosphere into the lithosphere. Taphonomic studies are key to paleobiology, paleontology, archaeology, geology, and geography, among other disciplines, as they impinge directly on our capacity to reconstruct paleoenvironments and past biotas. They do so by understanding the postmortem processes on biological materials and how they affect the fossil record—broadly defined as the set of non-living remains and traces of organisms—and the information therein.

The term *taphonomy*, from the Greek *taphos* and *nomos* (the “laws of burial”), was coined by Ivan Efremov in 1940, although such inquiries had been carried out well before, notably by German paleontologists in the late 19th and early 20th centuries. These researchers focused primarily on paleoenvironmental reconstruction, while Efremov and others emphasized information loss and biases introduced in the fossil record. Other researchers, especially after the input by Anna Behrensmeyer, Susan Kidwell, and Diane Gifford, have focused on the “positive” contributions of taphonomy as well. These emphasize the preservation of the fossil record and the paleoecological

and paleobiological information contained in the signatures of the processes that have affected it through time. Moreover, all the recycling pathways of biologically derived materials are informative to taphonomic enquiry.

The processes affecting organic remains from death to final burial, such as carnivore scavenging of vertebrate carcasses, are different from those occurring from final burial until recovery, as is the case with mineral replacement in different organic remains. The former are known as biostratinomy and the latter, as diagenesis, and both constitute taphonomy. On infrequent occasions, as in the case of severe floods and catastrophic death, rapid burial of organisms lead to large concentrations of exceptionally well-preserved fossils, known as fossil *lagerstätten*.

Taphonomists study both direct and indirect evidence—that is, not only the organic remains themselves but also the traces of different organisms, such as the tooth marks of a predator on bones or a leaf imprint on a sedimentary matrix. These traces or signatures of activity by an organism are also known as ichnofossils and commonly inform us of the interactions with its environment. Finally, they study the geological context where the fossils and traces are deposited as well.

To understand and interpret all these lines of evidence, taphonomic principles are needed. As in other historical sciences, the most powerful

strategy for doing so is actualism—that is, the study of contemporary, observable taphonomic processes producing effects analogous to those observed in the fossil record, and their causes. This strategy has been key in taphonomy since the German *Aktuopaläontologie* (invertebrate) program in the early 20th century. Observing present-day processes and their contexts links causes and effects, thereby generating models that can be applied to the fossil record by analogy. In some cases, experiments can help understand the effects of some processes as well. Such studies require assuming that the processes operating in the past are essentially the same as those operating in the present, although their rates and configurations and their interactions may well have changed through time. This methodological assumption is called uniformitarianism.

Another important strategy is the comparative method, namely, the comparison of different fossil records, which allows considering processes at a larger scale of operation. Deductions from general models and strong links among different lines of evidence complement both strategies.

All these approaches allow reconstructing and interpreting the taphonomic histories of different fossils. It should be noted that each specimen—that is, an individual organic remain or trace—has its own history, which can differ from that of other specimens in the same assemblage. Some variables, such as morphological and qualitative ones (e.g., chemical alterations), are monitored on each specimen. Other variables, though, such as the quantitative and contextual ones (e.g., the spatial relationships among different specimens), can only be assessed at the assemblage level. Therefore, analysis always begins at the specimen level, while fossil assemblages, with their specific properties—such as specimen arrangement, statistical trends in specimen properties, and the paleoecological information they bear—turn out to be the main unit of analysis and comparison. The geological context bearing the assemblages provides important, independent evidence as well that helps infer the taphonomic history of the fossil record, for instance, by shedding light on the accumulation processes that concentrated the fossils under study. All these lines of evidence can be

integrated at the landscape level so as to interpret taphonomic patterns and processes at a regional scale.

A more general approach considers taphonomic modes, which encompass fossil records resulting from similar processes (physical, chemical, and biological), involving similar preservational contexts. Hence, different taphonomic modes are characterized by different biases. Changes through time in taphonomic modes would thus generate megabiases.

One particular taphonomic mode is archaeological accumulations, where humans are the main taphonomic agents. These can be isolated or can even modify whole landscapes, as in the case of shellmound concentrations in coastal Brazil and Uruguay. Humans can not only be taphonomic agents but also the subject of taphonomic processes, as has been studied by forensics and paleoanthropology, two disciplines where taphonomy is also central.

It is the multidisciplinary nature of taphonomy, whereby very different questions are posed at varying scales, that contributes to the richness of this research field.

TAYLOR, GRIFFITH (1880–1963)

Thomas Griffith Taylor was an important figure in early-20th-century geography as an advocate of the doctrine of environmental determinism and social Darwinism.

British by birth, his family moved to New South Wales, Australia, when he was a young teenager. He earned a BSc at Sydney and returned to Cambridge for his BA. Trained in engineering, geology, and meteorology, he was selected from 7,000 applicants to serve on Robert Scott's ill-fated Antarctic Terra Nova Expedition in 1911, focusing on that continent's influence on Australia. He led a second expedition there later that year and drew some of the first maps of that continent. On his return to Australia, he assisted with the survey of the site for the new federal capital, even suggesting the name Canberra (of Aboriginal significance). He founded the New South Wales Geographical Society and was the founding editor of the journal *Australian Geographer*. In 1911, he published *Australia in Its Physiographic and Economic Aspects*. He earned a doctorate in geology from the University of Sydney in 1916, using his Antarctic research for his dissertation, and 4 years later, he became the founding head of that institution's geography department, Australia's first, and the McCaughey professor.

Taylor soon became known for his controversial support for environmental determinism, which he liberally laced with racism. He consistently advocated pseudoscientific notions that intelligence was correlated with skin color or the shape of skulls. Justifying the white conquest of the continent as an inevitable result of white racial superiority, he consistently portrayed Australia as too dry and harsh for the large numbers of immigrants seeking entry, in opposition to the boosterist "Australia Unlimited" school of thought. Taylor emphasized the region's limited carrying capacity, arguing that it was essentially a desert capable of supporting no more than 20 to 30 million people, and he was often criticized for an overly pessimistic reading of the continent's economic potential and population limit. His textbook espousing this view was banned in some school districts.

From the specific instance of Australia, he began to generalize to the wider world, theorizing links between race, nationality, migration, and climate. His major work on this topic was *Environment and Race* in 1927, which was widely read and translated into several languages. In *Australia: A Study of Warm Environments and Their Effect on British Settlement*, published in 1940, he put forth the opinion that the optimal course for a country to follow is dictated by the natural environment and that human deviations from this trajectory inevitably led to lower levels of social and economic development.

Frustrated by the university's denial of promotion, he left Australia to become professor of geography at the University of Chicago in 1929, and in 1935, at the initiative of the famed economist Harold Innis, he left for the University of Toronto, where he founded the geography department and remained until 1951. In 1941, he became president of the Association of American Geographers, the first non-American to hold that post; later, he was also elected president of the Canadian Association of Geographers. Over his career, he published 20 books, including his autobiography, *Journeyman Taylor*, and roughly 200 journal articles. After retirement, he returned to Australia, where he became a hero to those opposed to nonwhite immigration, and in 1959, he became president of the Institute of Australian Geographers. He died in 1963 and was cremated.

TAYLOR, PETER (1944–)

Peter J. Taylor is one of the most prominent contemporary human geographers. Born in England in 1944, he earned his BA (1966) and PhD (1970) from the University of Liverpool. His record of scholarship spans more than 40 years and currently includes more than 300 publications, some of which have been translated into as many as 23 different languages. Taylor has contributed to a range of subdisciplines within human geography, most notably in political and urban geography. Indeed, Taylor is recognized as a key figure in the development of political geography as a thriving subdiscipline and is a founding editor of the journal *Political Geography*.

While his contributions to political geography are myriad (indeed, the limited space afforded here cannot adequately do justice to them), he is perhaps best known for integrating world-systems analysis with political geography. His interest in world-systems analysis began as he sought to incorporate political economy into political geography, a subdiscipline he once critiqued as ironically being the most “apolitical” component of human geography. Taylor’s emphasis on world systems opened new spaces for critically assessing and modeling global interstate relations within the context of global cores and peripheries. This project in many ways demystified the development of the modern nation-state as a “container” of social, economic, and cultural forces, on the one hand, and the global liberalization of trade in recent decades known as globalization, on the other. Most recently, Taylor has further used a world-systems approach to investigate global structures of capital flows, contributing to understandings of the rise, and functioning, of “world cities” as command centers of global capital.

These two-tiered thrusts of research—global interstate relations and world cities—coincide with an earlier call by Taylor to reconsider prevailing notions of scale. Taylor proposed that scale be reconceptualized as encompassing three interlocking or interconnected realms: (1) a realm of everyday experience occurring at the level of the “urban,” (2) a realm of ideology encompassing the nation-state, and (3) a universal level of the capitalist world economy in which the previous two are situated. While this scalar hierarchy of realms has come under critical reassessment in recent years, Taylor is credited with launching an important and ongoing debate that has deepened and nuanced a concept of scale that was often akin to cartographic scale and was otherwise taken for granted among human geographers.

TECHNOLOGICAL CHANGE, GEOGRAPHY OF

Technological change is a direct driver of economic growth. New technologies allow societies to produce existing goods more efficiently and also open up entirely new and previously unimagined possibilities. It was technological change that largely eliminated the persistent cycles of famine and overpopulation that plagued humanity before the Industrial Revolution. Since that time, technology has facilitated an unprecedented expansion of standards of living. Simply put, current incomes as well as levels of health and amounts of leisure time for many people, particularly in the First World, are dramatically better than they were as recently as 150 years ago, and in many ways technological change is largely responsible.

Nonetheless, not everyone has made use of technology as well as today's developed economies. Great disparities in per capita income and other measures of well-being divide developed from developing economies, and technology's uneven geography is central to understanding why this remains so. Moreover, the geography of technological change has important implications for the changing shape of the increasingly interconnected global economy.

Technology: A Unique Component of Production

The word *technology* typically describes a material item, such as an oven or a computer. Academics, however, define technology differently—that is, as the set of rules and ideas that direct the production of an oven, computer, or other economically meaningful products. Under this definition, a technology is like a recipe used in the kitchen. A given technology will call for raw or semifinished materials as ingredients. To carry out the recipe and create a finished product, people apply their skills (human capital), tools (physical capital), and labor. Among these required components, capital, labor, and raw materials are all mostly privately held. Technology, however, bears some resemblance to a public good.

Two characteristics distinguish public from private goods: nonrivalry and nonexcludability.

To grasp technology's quasi-public nature, consider computers, mobile phones, and other electronic devices that contain semiconductors. Semiconductors in turn are the product of a particular set of rules and ideas about electrical conductivity. Like all technologies, the ideas that permit the building of semiconductors are nonrivalrous, meaning that one person's sharing the recipe for semiconductors with another will not diminish the owner's knowledge of it (unlike, say, sharing a private good such as a sandwich, which leaves less for the owner). The technology is also at least partially nonexcludable: It is hard for the owner to prevent another from learning about semiconductors, such that the acquirer might employ them for his or her own gain.

If technologies were "pure" public goods, a new and better semiconductor design created in one location would be immediately, costlessly, and universally available. Entrepreneurs in Paris and Bengaluru could instantly apply the electronic innovations that researchers produced in San Jose. Technology would be without meaningful geographical dimensions because of its perfect nonexcludability. Do we live in that kind of world? One way to answer this question is to compare countries' overall technology levels. Researchers often estimate levels of technology using "total factor productivity" (TFP), which accounts for the efficiency with which an economy or industry combines its factors of production. Simply, an economy with higher TFP can produce more output with less input because its deployment of technology is more sophisticated. TFP is not a perfect measure of technological sophistication, since nontechnological factors might cause these efficiency differences, but it is the most widely accepted indicator available. Table 1 shows TFP levels as ratios to the U.S. level for a handful of economies. Note the large gap between the United Kingdom and India. The United States, Italy, France, and the United Kingdom have productivity levels that are roughly comparable with one another. But each is between four and seven times the level of productivity enjoyed by India, China, Kenya, and Zaire. By this measure, rich countries are much more technologically advanced than poor countries, and these large differences remain even when we control for differences in the kinds of goods that

Country	TFP
United States	1.000
Italy	1.207
France	1.126
United Kingdom	1.011
India	0.267
China	0.106
Kenya	0.165
Zaire	0.160

Table 1 Total factor productivity (TFP; country/U.S. ratio) for selected countries, 1988

Source: Adapted from Hall, R. E., & Jones, C. J. (1999). Why do some countries produce so much more output per worker than others? *Quarterly Journal of Economics*, 114(1), 83–116.

countries make. For example, even if international productivity levels for a particular industry are compared, rich economies tend to be more productive than poor ones. This kind of evidence suggests that we do not live in a world where technology is a pure public good.

Technology Diffusion

If technology is not a pure public good, then how excludable is it? Since the 1950s, economic geographers have sought to measure the spread of technology among people and across space, an idea commonly termed *technology diffusion*, or *knowledge spillovers*. Some researchers traced the proliferation of individual innovations: Zvi Griliches, for example, conducted a pioneering study of American farmers' adoption of hybrid corn seeds in the early 20th century. Others examined patterns of collaboration between scientists and innovators. In general, these studies confirm that technologies diffuse across space but usually do so slowly and unevenly.

One reason why technologies do not circulate freely is that their creators actively seek to contain them. Innovators typically spend a great deal of time, effort, and expense to produce new technologies, and they want to make sure that they reap the rewards. To protect their intellectual property, they might take out a patent that legally mandates that others must pay to use it. They might also engage in secrecy and other less formal means of protection. Hence, an uneven pattern of

technological diffusion might result from a creator's desire to protect his or her technological investment.

Some studies of innovation suggest a more subtle reason that leads to a distinctive spatial pattern of diffusion. Most new technologies are not produced by lone scientists in dustfree laboratories but rather are the result of collective efforts that span organizations. These collaborations can be legally specified joint ventures, but they also frequently arise from casual interactions. Anna-Lee Saxenian discovered this notion in her study of Silicon Valley in the 1980s and 1990s. She learned that local computer engineers and entrepreneurs exchanged vital information at places such as the Mountain View's Wagon Wheel Bar. Silicon Valley's global technological leadership was constituted as much through these informal information-sharing links as by connections to Stanford University. The resulting social system permitted rapid transmission of ideas and generated specific cultural norms of collaboration and competition that helped propel Silicon Valley's firms to the leading edge of computer technology and to keep them there. Moreover, this system of localized, informal, insider knowledge meant that entrepreneurs in Paris and Bengaluru were in an important sense "locked out" of the conversation by their distance. Without the required geographically localized relationships, they were not privy to the exchange of information, and they lacked the cultural norms to participate.

To understand the importance of being in the right place, consider technologies dependent on two different kinds of knowledge or ideas. Codified knowledge is akin to the kind of recipe found in cookbooks, which contain a well-defined list of ingredients in the right proportions and offer careful instructions on how to combine them. Professional chefs, however—those who *create* new recipes and are responsible for culinary innovations—are more likely to employ tacit knowledge. Their procedures may have some loose structure that can be put down on paper, but they depend on their experience and creativity to fill in the blanks and bring it all together. Tacit knowledge is hard to turn into a blueprint that can be shared with anyone, because it depends on practice, trust, and acculturation. But two skilled chefs working in the same restaurant

might quickly and easily convey the needed information so that they could work together to produce a new dish. Tacit knowledge is often associated with innovation and new ideas, while technologies that have been with us for some time find their knowledge becoming increasingly codified. Some tasks, however, such as the job of a professional chef, demand tacit knowledge that can never be fully codified.

What geographical pattern does the distinction between tacit and codified ideas suggest? Codified technologies can be easily exchanged across space. Producers in one part of the world send rigorously specified blueprints for automobile parts to far-flung global suppliers, and they can reasonably expect the suppliers to closely adhere to the requirements. If a supplier fails, myriad competitors are capable of following the recipe. As a result of this intense competition, the production of products whose technology is fully codifiable is likely to occur wherever the cost is lowest. Codified technologies lead to a lowest-cost geographical pattern.

In contrast, tacit knowledge has a high degree of excludability; only individuals with certain shared characteristics can easily exchange it. This common frame of reference is most often born of repeated face-to-face encounters, such as the ones at the Wagon Wheel. As a result, tacit knowledge is typically produced and held in constrained geographical spaces. In addition to Silicon Valley's technology firms, we can see further evidence of this spatial clustering around relationships, complex tasks, and innovations among investment bankers in London, film and television workers in Los Angeles, and fashion designers in Paris. More systematic evidence emerges from examining patent citations. When someone files a patent for a new technology, he or she must cite the patents of other inventors on which the new invention is based. An inventor might cite patents held by scientists working anywhere in the world. But citations indicate strong geographical patterns: Inventors are most influenced by the work of nearby colleagues. In contrast to codified forms of knowledge, technologies dependent on tacit knowledge are therefore likely to lead to highly clustered geographical forms.

Spatial clustering because of tacit knowledge helps explain why cities exist and grow.

Individuals and firms continue to be drawn to dense urban areas to be "in the know." Urban regions are filled with people interacting face-to-face, exchanging ideas, and building social networks. Even in an age of instant messaging and social networking Web sites, engineers and entrepreneurs brave sky-high real estate prices in Silicon Valley to gain access to the social networks and tacit knowledge it contains.

Knowledge-based geographical clustering is also part of the reason for the large differences in economic well-being. Since technology dependent on tacit knowledge is hard to imitate, its producers are to some extent insulated from the kind of lowest-cost competition facing those using recipes that are more easily codified. In aggregate, this means that those regions and nations where new and complex technologies are being produced will typically enjoy high per capita incomes. In this way, technology's uneven geography leads to disparities in people's standards of living.

Globalization and the Geography of Technological Change

Can this uneven pattern of technological change and income continue in the Internet age as international trade ties far-flung economies ever closer together? Is globalization withering technology's excludability, taking it ever closer to the status of a pure public good? With a new generation as comfortable communicating online as off-line, there might come a day when relationships are as easily formed across the world as across a hallway. If this day comes, then technology's geography could conceivably disappear.

But most scholars agree that this situation has not arrived yet. In fact, the world might even be headed in the opposite direction. Greater trade and better communication technologies make it easier for everybody to specialize in what they do best and to farm everything else out to others who can excel in the remaining tasks. Edward Leamer notes that this is leading to a spatial division between "geek work" and "manly work." Advanced economies such as the United States are increasingly dedicated toward skilled "geek work": complex tasks with a high tacit knowledge content. Developing countries are focused on unskilled or semiskilled "manly work," such

as manufacturing and agriculture, which depend more heavily on codified technology. Hence, the emerging geography of technological change might be one in which innovation-oriented tasks and routine production-oriented tasks are increasingly spatially disparate. And proximity to the site of technological change matters for learning and income growth. A more optimistic view is that production and innovation are complementary. Developing economies are exposed to new ideas when they get involved in new forms of production. They might yet learn from these experiences and spawn new, world-changing ideas that shift the geographical center of tacit knowledge.

TELECOMMUNICATIONS AND GEOGRAPHY

Telecommunications have a long history of folding and reshaping space that extends to the telegraph in the mid 19th century and the telephone in the late 19th and 20th centuries. Today, the collection, transformation, and transmission of large volumes of information constitute a fundamental part of contemporary economies. The majority of jobs in industrialized nations consist of information processing in one form or another. These functions have increased in importance as computing has dramatically declined in cost and risen in power, the production of all goods and services has become more information intensive, technological change accelerated, product cycles shortened, and a deregulated, worldwide market has increased uncertainty and accelerated the competition among places for investment and jobs.

Information systems used to be confined to simple telephone service. For many decades, during which AT&T enjoyed a monopoly over this industry in the United States (and similar monopolies applied in other countries) and there were few incentives for change, the primary focus was on guaranteeing universal access, resulting in 95% penetration rates among U.S. households (second only to the television). During the 1980s and 1990s, as the cost of computing capacity dropped rapidly, communications became the largest bottleneck for information-intensive firms. Simultaneously, the microelectronics revolution unleashed a series of new technologies, including microwave, fiber optics, and satellites, that have increased the power, sophistication, and diversity of telecommunications qualitatively. With the digitization of information, telecommunications

merged with computers to form integrated networks, most spectacularly through the Internet. Technologies such as Electronic Data Interchange (EDI) and wireless services are becoming increasingly popular.

Misconceptions About Telecommunications and Geography

There exists considerable confusion about the real and potential impacts of telecommunications on urban structure, in part due to the long history of exaggerated claims made in the past, particularly by those subscribing to the “postindustrial” theory. Often, such views hinge on a simplistic and utopian technological determinism that ignores the complex, often contradictory relations between telecommunications and local economic, social, and political circumstances.

For example, repeated proclamations that information systems would allow everyone to work at home via telecommuting, dispersing all functions and spelling the obsolescence of cities, have fallen flat in the face of the persistence of growth in dense urbanized places. In fact, advances in videoconferencing notwithstanding, telecommunications are generally a poor substitute for face-to-face meetings, the medium through which most sensitive corporate interactions occurs, particularly when the information involved is irregular and unstandardized in nature. Most managers spend the bulk of their working time engaged in face-to-face contact, and no electronic technology can allow for the subtlety and nuances critical to such encounters. For this reason, a century of technological change, from the telephone to fiber optics, has left most high-value-added, white-collar, and administrative command-and-control functions clustered in downtown areas (despite their high rents), their agglomerative advantages intact if not unchallenged. In contrast, telecommunications are ideally suited for the transmission of routinized, standardized forms of data such as back office clerical functions. In short, contrary to much received opinion, there is no a priori reason to believe that telecommunications inevitably lead to the dispersal or deconcentration of functions; by allowing the decentralization of routinized functions, information technology

may enhance the comparative advantage of inner cities (albeit with jobs generally filled by suburban commuters). Information systems thus allow for the simultaneous concentration and deconcentration of economic activities.

Fiber Optics

The core of the global telecommunications infrastructure is an extensive and seamlessly integrated network of fiber-optic lines—long, thin, flexible, and highly transparent rods of quartz glass (or less commonly, plastic) about the thickness of a human hair that can transmit light signals through a process of internal reflection, which retains light in the core and transforms the cable into a waveguide. They can transmit voice, video, or data traffic at the speed of light; because light oscillates much more rapidly than other wavelengths, such lines can carry much more information than other types of telecommunications. Modern fiber cables contain up to 1,000 fibers each and are ideal for high-capacity, point-to-point transmissions. Indeed, far more than any other technology, such as copper cables, microwaves, or satellites, fiber optics supply the vast bulk of data, voice, and video transmission services around the world. Because of their capacity to deliver high volumes of information rapidly and securely (e.g., via broadband), fiber optics cables form the backbone of the Internet as well as private corporate lines and are widely used in the electronic media for commercial and residential purposes (e.g., cable television).

Today, the world’s fiber system totals more than 25 million km (kilometers) in length, connecting all the world’s continents except Antarctica (Figure 1). The geography of global fiber networks centers primarily on two distinct telecommunications markets across the Atlantic and Pacific Oceans, connecting two of the major engines of the world economy, North America and East Asia. In 1988, AT&T initiated the world’s first transoceanic fiber-optic cable, Trans-Atlantic Telecommunications (TAT-8), which could carry 40,000 telephone calls simultaneously. The Trans-Atlantic line was the first of a much broader series of globe-girdling fiber lines that AT&T erected in conjunction with a variety of local partners. Because large corporate users

Figure 1 The world's major fiber-optic cables, 2006. Fiber has displaced other forms of telecommunications to become the world's leading method of transmitting information.
Source: Author.

are the primary clients of such networks, it is no accident that the original and densest web of fiber lines connects London and New York, a pattern that extends historically to the telegraph and telephone. The next generation, TAT-9 and TAT-10, which began in 1992, could carry double the volume of traffic of TAT-8. The third generation, TAT-11 to TAT-13, was the first to use the erbium-doped fiber amplifier rather than the older repeaters. Newer generations of cable were even more powerful. Starting with the Trans-Pacific Cable (TPC-3) in 1989, connecting New York and Tokyo, a growing web of Trans-Pacific lines mirrored the rise of East Asian trade with North America, including the surging economies of the newly industrialized countries. The complex interplay of deregulation, globalization, and technological change increased the international transmission capacities and traffic volumes for fiber-optic carriers explosively.

In addition, fiber lines have extended into several newer markets. In 1997, AT&T, NYNEX, and several other firms (including, for the first time, nontelecommunications firms) opened the self-healing Fiberoptic Link Around the Globe (FLAG), a system that eventually expanded to 55,000 km, connecting Europe and southeast Asia. The world's longest submarine telecommunications network, FLAG, the world's longest submarine telecommunications cable, filled a void in undersea cable capacity between Europe, the Middle East, and Asia. In Africa, long marginalized in global telecommunications, AT&T's \$2 billion Africa ONE (Optical NETwork) system circumnavigates the continent with a 39,000-km, high-capacity, self-healing undersea fiber-optic network.

Telecommunications and Finance

Telecommunications have had their most important impacts in the capital markets. Banks, insurance companies, and securities firms, which are generally very information intensive in nature, have been at the forefront of the construction of an extensive network of leased and private communication networks. Electronic funds transfer systems, in particular, which form the nerve center of the international financial economy, allow banks to move capital at a moment's notice, arbitraging interest rate differentials,

taking advantage of favorable exchange rates, and avoiding political unrest. Such networks give banks the ability to move money—by some estimates, more than \$2 trillion daily—around the globe at stupendous rates (the average trade takes less than 25 seconds). Subject to the process of digitization, information and capital become two sides of the same coin.

In the securities markets, global telecommunications systems have facilitated the emergence of 24-hr./d (hour per day) trading, linking stock markets through computerized trading programs. The ascendancy of electronic money has shifted the function of finance from investing to transacting, institutionalizing volatility in the process. Traveling at the speed of light, as nothing but assemblages of zeros and ones, global money performs a syncopated electronic dance around the world's neural networks in astonishing volumes. The world's currency markets, for example, dwarf the funds that change hands daily to cover global trade in goods and services. National boundaries mean little in this context: It is much easier, say, to move \$1 billion from London to New York than a truckload of grapes from California to Nevada.

As large sums of funds flow with mounting ease across countries' borders, national monetary policies became increasingly ineffective, making monetary controls over exchange, interest, and inflation rates progressively difficult to sustain. In the United States, for example, the Federal Reserve, alarmed at the prospect of inflation, changed the reserve ratio of banks numerous times in the 1990s and 2000s, only to find that its control over the national money supply had diminished severely. This is not to say that nation-states enjoy no leverage whatsoever over such factors, but the steady convergence of short-term interest (but not profit) rates globally undoubtedly reflects the mounting ease with which capital transcends national borders.

Another way in which telecommunications have affected the financial industries is through the growth of offshore banking, a reflection of the broader shift from traditional banking services (loans and deposits) to lucrative nontraditional functions, including debt repackaging, foreign exchange transactions, and cash management. Usually introduced in response to favorable tax laws, offshore banking has become important to

many microstates in the Caribbean (e.g., Cayman Islands, Bahamas, Panama), Europe (e.g., Gibraltar, Luxembourg, the Isle of Man, Liechtenstein), the Middle East (e.g., Cyprus, Bahrain), and the South Pacific (e.g., Vanuatu). Thus, as the technological barriers to moving money have fallen, legal and regulatory ones have increased in importance, dispelling simplistic assertions about the “death of geography.”

Other applications of telecommunications in finance include Electronic Data Interchange (EDI) systems, which allow information to move directly among computers, including data, forms, funds, invoices, and text. In insurance, these systems have streamlined underwriting policies, and centralized database management systems have minimized data redundancy and allowed for updates irrespective of the data's physical location. Networks such as the Internet even allow professionals to move into rural areas.

Telecommunications and Global Cities

One of the most significant repercussions of the growth of financial markets has been the growth of “global cities” or “world cities,” notably London, New York, and Tokyo, each of which seems to be as attuned to the rhythms of the global economy as the nation-state in which it is located. At their core, global cities allow the generation of specialized expertise on which so much of the current producer services economy depends. Furthermore, each city is tied through vast tentacles of investment, trade, migration, and telecommunications to clients and markets, suppliers and competitors, and consumers and producers around the world. Each metropolitan area seems to be as attuned, if not more so, to the global economy as the nation-state in which it is located. While several other cities (e.g., Paris, Toronto, Los Angeles, Osaka, Hong Kong, and Singapore) certainly can lay claim to being national cities in a global economy, the trio of New York, London, and Tokyo has played a disproportionate role in the production and transformation of international economic relations in the late 20th century. London, for example, boomed under the impetus of the Euromarket in the 1980s and has become increasingly detached from the rest of Britain. New York rebounded from the crisis

of the mid 1970s with a prolonged bull market on Wall Street facilitated by electronic trading. Tokyo, despite the woes of the Japanese economy, remains an important center of financial activity and home to many of the world's largest banks by asset value. In each city, a large agglomeration of banks and related firms generates well-paying jobs; in each, soaring incomes for a wealthy stratum of traders and professionals has lifted real estate prices to astronomical levels. The primacy of global cities, and their unique niche internationally, hinges largely on their role as producers and conveyors of specialized pools of information. All three metropolises are endowed with enormous telecommunications infrastructures that allow corporate headquarters to stay firmly in touch with global networks of branch plants, back offices, suppliers, clients, subcontractors, subsidiaries, and competitors. This phenomenon illustrates how geographic centralization can be facilitated, not eradicated, by telecommunications.

However, telecommunications simultaneously threaten the agglomerative advantages of dense urban areas, particularly the advantages of face-to-face communications. This trend is particularly evident in finance—the bread and butter of global cities. For example, the National Automated Dealers Quotation System (NASDAQ) has emerged as the world's largest stock market; unlike many other exchanges, NASDAQ lacks a trading floor, connecting millions of traders worldwide through fiber-optic lines in the over-the-counter market. Similarly, Paris, Belgium, Spain, Vancouver, and Toronto all recently abolished their trading floors in favor of screen-based trading.

Back Office and Call Center Relocations

Few domains of economic activity have been as heavily affected by telecommunications as the low-level, routinized back office functions. Back offices perform clerical functions such as data entry of office records, telephone books, library catalogs, stock transfers, payroll or billing information, bank checks, insurance claims, and magazine subscriptions. These tasks involve unskilled or semiskilled labor, primarily women, and frequently operate on a 24-hr./day basis. Back offices have few of the interfirm linkages associated with

headquarters activities and require extensive data-processing facilities, reliable sources of electricity, and sophisticated telecommunications networks.

Historically, back offices have been located adjacent to headquarters activities in downtown areas to ensure close management supervision and rapid turnaround of information. However, under the impetus of rising central-city rents and shortages of sufficiently qualified (i.e., computer-literate) labor, many service firms began to uncouple their headquarters and back office functions, moving the latter out of the downtown to cheaper locations on the urban periphery. Most back office relocations, therefore, have been to suburbs.

Given the increasing locational flexibility afforded by satellites and a growing web of inter-urban fiber-optics systems, back offices have begun to relocate on a much broader, continental scale. Under the impetus of new telecommunications systems, many clerical tasks have become increasingly footloose and susceptible to spatial variations in production costs. New digital call distribution systems have made possible the relocation of phone services that were once confined to centralized locations. Internationally, this trend has taken the form of the offshore office. The primary motivation for offshore relocation is low labor costs, although other considerations include worker productivity, skills, turnover, and benefits. Offshore offices are established not to serve foreign markets but to generate cost savings for U.S. firms by tapping Third World labor pools, where wages are as low as one fifth of those in the United States. Notably, many firms with offshore back offices are in industries facing strong competitive pressure to enhance productivity, including insurance, publishing, and airlines. Offshore back office operations remained insignificant until transoceanic fiber-optic lines made possible geographic flexibility on an international scale. Such functions either may be subsidiaries of multinational firms or they may operate under contract with U.S.-based businesses. Inputs, usually documents or magnetic tapes, are sent by air to offshore processing facilities (e.g., via Federal Express). After processing, generally a few days at most, the results are returned via satellite or dedicated telephone or fiber-optic line. Thus, the capital investments in such operations are minimal, and they possess great flexibility, maximizing

their ability to choose among locations based on slight variations in cost or profitability.

Several New York-based life insurance companies have erected back office facilities in Ireland, with the active encouragement of the Irish Development Authority. Often situated near Shannon Airport, they move documents in by Federal Express and the final product back via satellite or one of the numerous fiber-optic lines that connects New York and London. Likewise, the Caribbean, particularly Anglophone countries such as Jamaica and Barbados, has become a particularly important locus for American back offices. American Airlines paved the way in the Caribbean when it moved its data processing center from Tulsa to Barbados in 1981; through its subsidiary Caribbean Data Services, it expanded operations to Montego Bay, Jamaica, and Santo Domingo, Dominican Republic, in 1987. In Asia, Manila, Philippines, has emerged as a back office center for British firms, with wages 20% of those in the United Kingdom. Such trends indicate that telecommunications may accelerate the offshoring of many low-wage, low-value-added jobs from the United States, with dire consequences for unskilled workers in the home country.

A similar form of low-wage, low-value-added services involves centers of telework, often labeled call centers. Call center functions include telemarketing, customer assistance, and phone orders, often with designated 1-800 numbers. They range greatly in size, from as few as five to as many as several thousand employees. Like back offices, call centers are primarily screen based and do not require proximity to clients. The major cost consideration is labor, although the workforce consists primarily of low-skilled women and high turnover rates are common. They are thus the epitome of a footloose industry, disembedded from their local milieu and highly mobile. There are an estimated 80,000 to 100,000 call centers within the United States, which employ between 3% and 5% of the national labor force, the majority of which are located in urban or suburban locations. Like back offices, call centers have become increasingly globalized. India, for example, has attracted a significant number of customer service centers near its software capital Bengaluru, where workers are trained to speak in the U.S. dialect of English and are able to gossip

with customers about pop culture. Wages there, which average US\$2,000 per year, are higher than average Indian salaries but are only 10% of what equivalent jobs pay in the United States.

Urban Telecommunications Infrastructures

Urban infrastructure investments in communication technologies have by and large remained surprisingly unimportant to policymakers. While many cities and localities are willing to invest in new roads or water control projects, urban planners and economic development officials have often overlooked or ignored altogether the role that telecommunications can play in stimulating economic growth. For example, only 5% of U.S. municipalities have explicit plans for telecommunications. One reason is that there is no statistical correlation between local investment in telecommunications and economic growth. However, while the telecommunications industry *per se* is relatively small and capital intensive, generating few jobs, and while telecommunications by themselves do not guarantee economic development, such systems have become necessities for many firms.

Although large cities typically have much better developed telecommunications infrastructures, the technology has rapidly diffused through the urban hierarchy and is becoming increasingly equalized among regions. In the future, therefore, the marginal returns from investments in this infrastructure are bound to diminish, minimizing competitive advantages based on an information systems infrastructure alone and forcing competition among localities to be based on other factors, such as the cost and quality of labor, taxes, and the regulatory framework. Regions with an advantage in telecommunications generally succeed because they have attracted successful firms for other reasons.

Telecommunications may affect the urban infrastructure in other, less obvious ways. One increasingly important effect of new information systems is “telework” or “telecommuting,” in which workers substitute some or all of their working day at a remote location (almost always home) for time usually spent at the office. The self-employed do not count as teleworkers because they do not substitute it for commuting. Telework

is most appropriate for jobs involving mobile activities or routine information handling, such as data entry or directory assistance. Proponents of telework claim that it enhances productivity and morale, reduces employee turnover and office space, and leads to reduction in traffic congestion (especially at peak hours), air pollution, energy use, and accidents. If this phenomenon grows as expected, it will lead to further decentralization of economic activity in suburban areas.

However, while telecommuting may reduce flows of people, flows of information can never be a substitute for flows of water, electricity, gas, goods, or trash. Indeed, there are countervailing reasons why telecommunications may, in apparent contradictory fashion, increase the demand for transportation rather than decrease it. First, it is not at all clear that telecommuters have shorter weekly commutes overall; indeed, by allowing them to live farther from their workplace, the total distances traveled may actually rise. Second, time freed from commuting may be spent traveling for other purposes, such as shopping or recreation. Telecommuting may alter the reasons for travel but not necessarily the frequency or volume. Third, by reducing congestion, telecommuting may lead to significant induced effects, whereby others formerly inhibited from driving may be induced to do so. In short, the substitutability, rather than complementarity, of telecommunications for commuting is far from clear.

Another potential, and growing, impact of information systems on urban form concerns transportation informatics, including a variety of improvements in surface transportation such as smart metering, electronic road pricing, synchronized traffic lights, automated toll payments and turnpikes, automated road maps, information for trip planning and navigation, travel advisory systems, electronic tourist guides, remote traffic monitoring and displays, and computerized traffic management and control systems, all of which are designed to minimize congestion and optimize traffic flow (particularly at peak hours), enhancing the efficiency, reliability, and attractiveness of travel. Wireless technologies such as cellular phones allow more productive use of time otherwise lost to congestion. Such systems do not so much incorporate new technologies as improve on the existing ones. In-vehicle navigation

systems with inboard computers, such as the Intelligent Vehicle Highway System currently under way in Southern California, represent the next generation of this technology.

Conclusion

The widespread adoption of telecommunications is reflective of a series of broader transformations in the world economy. Economic development officials can adapt their views to these changes by recognizing that economic activity has relatively little to do with the production of tangibles, such as in agriculture and manufacturing, and is dominated by invisible flows of data and capital, which the digital revolution has transformed into twin aspects of the same phenomenon—one that moves at the speed of light—giving firms unprecedented mobility and flexibility. Markets, labor processes, policy planning, and spatial structures have changed accordingly. Cities and regions can search for a competitive advantage in this world in several ways. In large metropolitan areas, buoyed by the historical legacy of dense nucleations of firms interconnected by face-to-face interaction, telecommunications have left agglomeration economies largely intact, albeit not unchallenged, as in the case of electronic screen trading of stocks. In some cases, information systems have contributed to a marked centralization of key activities in a handful of fortunate cities as firms consolidate operations in an attempt to derive economies of scale. Other services, however, that rely primarily on unskilled inputs of routinized information are increasingly vulnerable to substitution by new telecommunications systems, such as back offices. A key theme here, therefore, is that information systems tend to centralize high-wage, high-value-added, white-collar functions while decentralizing low-wage, low-value-added, blue (or pink) collar ones.

TELECONNECTIONS

Teleconnections are hemispheric-scale statistical relationships that result from the spatial interdependencies between the atmosphere and the ocean. In other words, teleconnections describe how atmospheric or oceanic circulation changes occurring at one location are linked to changes at other locations that are widely separated geographically. On the order of weeks to years, these global associations are recognized by an atmospheric circulation disturbance occurring at select locations or “centers of action,” thereby producing oscillations affecting weather patterns downstream. These action centers identify the climatological positions of low- and high-pressure areas associated with particular atmospheric teleconnection patterns or cold and warm sea surface temperature regions with oceanic teleconnection patterns. Frequently, atmospheric oscillations are strongly linked or coupled with oceanic changes. Locations in the vicinity of the action centers shift from characteristic climatologically normal conditions to distinct patterns of climate anomalies that

occur over a range of time periods. The climate anomalies produced by a teleconnection pattern depend on its phase, indicating the prevailing extremes in the action center variable. Teleconnection patterns represent a principal mode of annual large-scale atmospheric circulation variability that produces both short- and long-term regional climate effects.

Teleconnections are identified through statistical techniques demonstrating the degree to which fluctuations in a variable are related to two or more separate areas. Correlation analysis describes the strength and direction of association between paired variables, such as pressure changes in one location compared with all other locations. The El Niño Southern Oscillation (ENSO) is typically identified in this manner. ENSO is an interannual periodic abnormal warming or cooling of the eastern equatorial Pacific SSTs that is regularly accompanied by a shift in the typical surface pressure field between the Australian and Peruvian coasts, the primary action centers that are strongly negatively correlated. Eigenvector-based methods, such as principal component analysis, allow one to detect groups of interrelated variables, simplify the representation of the data field, and recognize similar regional modes of variability. The Pacific/North American pattern is often produced from eigenvector methods that distinguish three primary action centers across North America based on the cold season midtropospheric geopotential height field (i.e., the altitude of the 500- or 700-hectopascal pressure surface). Statistical methods such as these have been used to recognize sets of action centers unique to each teleconnection pattern.

The strength, phase, and location of the teleconnection pattern establish the geographical extent and severity of the climate impacts. For instance, strongly positive ENSO phases (or El Niño) during December to February are typically linked to increased precipitation in northwestern South America and the Southern United States, decreased precipitation in Northern Australia, and higher temperatures in northwestern Canada and South Asia; negative ENSO phases (or La Niña) usually have the reverse effects. The expected climate anomalies associated with a

teleconnection phase suggests a potential for increased long-range climate forecasting. Consequently, teleconnections has been a major component of atmospheric research in recent decades.

TELEVISION AND GEOGRAPHY

Over the past two decades, human geographers have taken an increasing critical interest in the mass media. This development reflects the growing recognition that the media are centrally implicated in both (a) the constitution, experience, and representation of space, place, landscape, and environment (in short, *geography*) and (b) the mechanisms by which geography in its various incarnations, in turn, is implicated in social processes. Of all the mass media, television is seen as perhaps centrally important in these regards; for, despite the rapid growth in penetration and usage of the Internet and notwithstanding the ongoing cultural, economic, and political significance of newspapers, magazines, and radio, it is widely believed that for the bulk of the world's population, television is the most socially *material* mass medium.

Geographers have studied television's social role from a large number of different angles, which can usefully be grouped into three categories, and it is around these three categories that this entry is organized. The first category is geographies *on* television—in other words, the ways in which geography (i.e., space, place, landscape,

and environment) is represented in television programming. The second category is geographies of television: what significant geographical patterns and processes can be identified in the organization of television itself as both an industry (which produces and distributes programming) and a technology (through which people receive and watch such programming). The final category is harder to define but can perhaps best be described as the myriad ways in which television shapes and reshapes the fundamental *experience* of space and place and of spatially mediated identities.

Geographies on Television

There is now a large and rapidly expanding literature dealing with the ways in which geographies are conveyed on screen. The literature shows that it pays to think closely about the representation of both generic and more specific geographies. Generic geographies include the following generalized places: the city, the suburbs, “nature,” the desert, the road, and “home.” By “specific” geographies, we mean actual real-world places situated at all manner of different scales: Africa, the Middle East, the United States, Northern England, Baghdad, Manhattan, and so on.

Just as geographers have been interested in a wide range of different geographies and their materialization in programming, so too have they analyzed these representations from a variety of different vantage points. Some of the analysis has been relatively straightforward—concerned “merely” with understanding how a particular space or place has been conveyed and what that representation tells us about the geography in question that we might not have known before. Increasingly, however, geographers have sought to read “back” from programming to the society that produces it. What can we learn from geography’s representation on television—its structure, form, contents, and even absences—about, for instance, the prevailing social constructions of race, gender, and class? Finally, geographers have sought to more directly link representation and “reality.” A good example of this has been work demonstrating how television’s representation of a particular place can radically alter social consumption (e.g., tourist visits) of that place.

Geographies of Television

The analysis of geographies of television has looked at television as a material *process* through all stages of its life span. These begin with *production*: Where is television programming filmed, and what notable trends can we discern in this respect? Here, for instance, one of the central themes of recent literatures has been to track the emigration of shooting from traditional locations—Hollywood being the archetypal example—to newer and often lower-cost sites, a development referred to as “runaway” productions.

After production, comes *packaging*: the editing and then bundling of programming into, most familiarly, television channels. Where does this activity—arguably the nerve center of the television industry—take place? It has been shown that it typically occurs in large industrial clusters or agglomerations, of which Hollywood is, again, the classic case. Allen Scott’s work has been seminal in demonstrating this idea.

The third link in the chain is *distribution* and its geographies. Once more, the literature on this topic is vast, but its central gist has been to show that on an international scale the main flow of programming has long been from the United States to the rest of the world—sparking, particularly in the 1970s and 1980s, repeated accusations of U.S. cultural imperialism. Since then, it has been shown that while the United States remains overwhelmingly dominant in global television trade, more complex interregional flows from multiple origins do exist and are rapidly proliferating.

The final important geography of television concerns its consumption. Here, especially in the work of David Morley, the emphasis has been on the consumption of television in the home—on family and the social relations of *domestic* space. But it has also been recognized that television long ago breached the boundaries of home—it is consumed in bars, in malls, in airports, and now on mobile phones and similar handheld devices. Discussion of these geographies has been an increasing focal point.

Television, Space, and Identity

Geography is itself produced and reproduced on television; television has its *own* geographies, and

A Turkish Cypriot shopkeeper watches the TV screens that show the Cyprus map and the news in the Northern Turkish part of divided Nicosia, April 22, 2004. The Greek and Turkish Cypriot communities voted in separate referenda on April 24 for the approval or rejection of the United Nations plans for the reunification of their war-divided island.

television also shapes and reshapes wider human geographies. This last claim potentially can mean many different things, but two are arguably important. First, watching television can affect how we experience space and place per se—and, moreover, how space interacts with time. Many influential authors have pondered on such themes and have offered arresting phrases to capture these experiential changes. John Thompson, for example, suggests that television and other electronic media have “uncoupled” time and space by breaking down what was traditionally a linear relationship between spatial and temporal distance. Along similar lines, the geographer David Harvey coined the popular phrase “time-space compression” to evoke the way in which the media have shrunk the world and the time taken to electronically navigate it.

Second, by reworking the experience of space and place, television also reshapes social identities that are themselves geographically grounded: identities such as nation, community, or, more broadly, “us” and “them.” Joshua Meyrowitz, for instance, famously argued that our social place and physical place in the world used to mutually reinforce one another but that by familiarizing us with places far away, television ruptured this symbiosis and has left us, literally, with “no sense of place.” Again, there is an enormous literature on such matters. But one example perhaps suffices to demonstrate the complexity of the relationships in question: satellite television. By allowing for single broadcasts that transcend traditional nation-state boundaries, satellite television can arguably lead to the dissolution of narrow, national, place-bounded identities. Equally,

however, satellite television can harden national identities precisely by virtue of its spatial scope—the identities, for example, of diaspora nations spread around the globe and traditionally fractured by space. It is just these types of complexities that geographers of television are increasingly grappling with.

TEMPERATURE PATTERNS

Global temperature patterns are primarily determined by the amount of solar radiation reaching Earth's surface, which in turn is influenced by factors such as latitude, the distribution of land masses and oceans, cloud cover, topography, and the circulation of the atmosphere and oceans. As solar radiation reaches the surface, it is absorbed—resulting in warming, reflected, or converted to latent heat in the evaporation of water. Surface temperature is thus determined by the flux of radiation to the surface and the disposition of this energy as it arrives.

Global temperature patterns are characterized by a latitudinal temperature gradient with colder temperatures toward the poles, greater temperature variability in high-latitude continental interiors as well as in arid regions, and cooler and more variable temperatures at high elevations. The primary controls on these patterns are latitude and land/water contrasts, with cloud cover, humidity, elevation, and large-scale circulation of the atmosphere and oceans contributing. This entry discusses the role played by these factors in determining temperature patterns.

Latitude and Temperature

The average surface temperature of Earth as a whole is 15 °C (59 °F), and the most obvious spatial pattern is a latitudinal gradient: Low-lying tropical regions near the equator typically experience annual average temperatures around 27 °C (81 °F), while high-latitude ice caps in Antarctica and Greenland have annual average temperatures below −40 °C (−40 °F). The seasonal variation in temperature will likewise differ significantly across the planet—low-latitude coasts will have seasonal temperature swings of less than 3 °C (37 °F), while high-latitude continental interiors will experience swings in excess of 40 °C (104 °F).

The latitudinal temperature gradient is due to the variation in the sun angle (the elevation of the sun above the horizon) between the equator and the poles. Earth is an oblate spheroid orbiting the sun at an average distance of 150 million kilometers (93 million miles). Due to the curve of the Earth, the noontime sun will pass directly overhead (the sun angle will be 90°) at a specific latitude, known as the solar declination, with lower sun angles at latitudes away from the solar declination. Due to the constant tilt of Earth's axis relative to the plane of the orbit, the solar declination cycles between the Tropic of Cancer (23.5° N) on the summer solstice to the Tropic of Capricorn (23.5° S) on the winter solstice, passes over the equator twice a year—once on each equinox.

Lower sun angles mainly result in cooler temperatures because the solar radiation is spread over a larger surface area when the sunlight strikes the surface obliquely. When the sunlight is thus diffused, less energy is absorbed per unit of surface and less warming occurs. Two additional

factors also contribute to cooler temperatures at higher latitudes: First, polar surfaces such as ice tend to have higher albedos, so a larger amount of insolation is reflected rather than absorbed. Second, radiation arriving with a low sun angle travels a longer, slanting path through the atmosphere than when the sun is directly overhead, and therefore, more energy is absorbed or scattered before reaching the surface.

Seasonal variability in temperature results from seasonal variations in the sun angle. As Earth orbits the sun, the solar declination latitude moves north and south, producing higher sun angles and warmer temperatures during the summer season. Outside the tropics, there is a 47° swing in noontime sun angle from summer to winter. In addition to sun angle, day length (hours of sunlight) varies from summer to winter, with larger variations at greater distances from the equator. At high latitudes, winters are characterized by short days and low sun angles, while in the summer the days are longer and the sun is higher. As a result, high-latitude locations experience large seasonal variations in temperature, with extremely cold winters and moderate summers. In contrast, at low-latitude locations, the sun remains relatively high above the horizon throughout the year, and seasonal changes in day length are small, resulting in reduced seasonal variation in temperature. Therefore, during winter, the extremely low temperatures at high latitudes result in a significant temperature gradient from the equator to the poles, while high-latitude warming during summer produces a reduced latitudinal gradient.

The Principle of Continentality

Another major factor affecting temperature variations is the difference in heating characteristics of land surfaces versus water surfaces—a set of processes referred to as the principle of continentality. Given the same amount of insolation, a land surface will heat up and cool off more rapidly than an ocean surface, resulting in greater diurnal and seasonal temperature variations in continental interiors compared with coastal locations. There are four key reasons for this difference: (1) the transparency of ocean water, (2) the mobility of ocean water, (3) the differing amounts of latent heat transfer from the two surfaces, and (4) the differences in the specific

heats of the surface materials. Because water is relatively transparent to solar radiation, incoming energy is absorbed throughout the top several meters of the water column. In contrast, insolation striking a land area is entirely absorbed at the surface itself. Because the energy received by the water surface is spread out over a larger volume of the material, the amount of warming experienced directly at the surface is reduced.

In addition to the penetration of solar radiation through the upper layers of the water column, the fluidity of water means that energy can be distributed deeper into the water column once it is absorbed. Thus, energy that might lead to increased warming during periods of high insolation may instead be circulated downward, and heat may circulate upward to moderate episodes of cooling. Land surfaces do experience some conduction of heat downward through the soil column, but the effect is relatively small—in general, energy absorbed at the land surface remains at the surface to produce warming.

A third factor contributing to continentality is the generally higher amount of evaporation that occurs from water surfaces. When water evaporates, energy is used to effect the change in state from liquid to gas. This energy, referred to as the latent heat of evaporation, is used to break the weak bonds between the water molecules and is stored in the higher-energy configuration of the water vapor. When the vapor condenses, the same amount of energy is liberated as the latent heat of condensation. The energy that is used for evaporation does not contribute to any sensible warming at the point of evaporation. Therefore, given the same amount of surplus radiation, a wet surface will experience less warming than a dry surface because a larger amount of energy will be transferred away as latent heat from the wet area. Over a dry surface, most of the surplus radiation will be converted to sensible heat, resulting in warming.

The final factor in the varying temperature responses between land and water surfaces is the difference in specific heat between the surface materials. Specific heat is the physical property of a substance that determines the amount of energy required to raise the temperature of the material. Water has a higher specific heat than land, which means that it takes more energy to produce a given amount of warming in a water surface.

Given the same input of insolation, therefore, a land surface will warm up more quickly than an ocean surface. Conversely, as the surfaces cool by radiating long-wave energy, the land will experience a larger drop in temperature than the water.

Taken together, these four factors produce larger diurnal and seasonal temperature variability in continental interiors compared with coastal locations. Combined with the latitudinal effect on temperature variability discussed above, the largest seasonal swings in temperature will occur at high-latitude continental interiors, for example, Eastern Siberia, and the lowest temperature swings will occur at low-latitude coastal and oceanic locations. Because the prevailing upper-level flow and storm movement in the mid and high latitudes is west to east, the cold dry air masses produced in continental interiors are pushed eastward, and so the most “continental” regions are in the eastern portions of the land masses. Conversely, the maritime effect is more pronounced on west coasts.

Cloud Cover and Water Vapor

A third major control on global- and regional-scale temperature patterns is the amount of cloud cover and water vapor. Clouds are a significant contributor to the planetary albedo and have an overall cooling effect of approximately 5 °C (41 °F) on the global average temperature. Due to the extensive cloud cover associated with the Intertropical Convergence Zone (ITCZ), latitudes near the equator are not the hottest part of the planet, despite the high sun angles. Rather, the hottest temperatures are found in the cloudfree subtropical latitudes (~30° N and S) under the tropospheric subsidence of the subtropical highs. While equatorial temperatures typically average around 27 °C (81 °F) throughout the year, summertime average temperatures in the subtropical deserts will exceed 40 °C (104 °F) in many places.

In addition to reflective cooling, clouds also have a warming effect on the surface as they absorb long-wave radiation leaving the surface and radiate energy back downward in what is referred to as the cloud-greenhouse effect. This effect is most pronounced with high thin clouds, which are effectively opaque to outgoing long-wave radiation but thin enough to pass solar radiation. The warming effect of clouds is particularly

noticeable at night, when only the warming process is operating. Therefore, although the overall impact of cloud cover is one of cooling, the local effect will vary between warming and cooling depending on the time of day and the type of clouds present. In terms of variability, cloud cover tends to reduce the diurnal temperature range as daytime temperatures are reduced by the reflection of insolation and nighttime temperatures are increased by the downward radiation of long-wave energy.

High levels of humidity in the atmosphere play a role similar to the warming effect of clouds, as water vapor is a potent greenhouse gas. In humid environments, long-wave radiation is absorbed as it propagates upward from the surface. The main impact of this is a sharp reduction in diurnal variability—humid and cloudy tropical regions may experience day-to-night temperature ranges as small as 5 °C (41 °F), while diurnal temperature swings of 30 °C (86 °F) are not uncommon in the dry desert areas.

Topography

Topographic features have an impact on temperature at a regional and local scale. Because the main source of heat for the troposphere is Earth’s surface, temperature decreases with altitude, and mountaintops have cooler temperatures than lowlands. In addition, the density and humidity of the atmosphere decrease at higher elevations, reducing the amount of outgoing long-wave radiation absorbed. Thus, high elevations cool rapidly over the nighttime, producing increased diurnal temperature ranges compared with lower regions.

Mountain ranges also affect regional temperature patterns through the production of rain-shadow deserts. Where topographical barriers lie across the prevailing wind flow, orographic uplift leads to cloud formation and precipitation on the windward side of the range. As the now drier air descends on the leeward side of the feature, it is warmed adiabatically, which results in warm arid conditions behind the mountain range.

Circulation of the Atmosphere and Oceans

A final factor that influences global temperature patterns is the large-scale circulation of the

atmosphere and the oceans, which is a product of the latitudinal energy gradient. Surplus energy from the lower latitudes is moved poleward through the atmosphere as well as via the major warm ocean currents, such as the Gulf Stream, found on the western margins of ocean basins in the midlatitudes. This shift of energy produces some warming at the higher latitudes and helps explain why Western Europe has a somewhat more temperate climate than latitude alone would suggest.

TEMPORAL GIS

Temporal geographic information systems (GIS) (also known as spatiotemporal GIS) is a concept and an active area of research within geographic information science focusing on representation, management, manipulation, and analysis of spatiotemporal data. Time presents an important component of spatial analysis. However, conventional GIS approaches adopt a static view to model time-dependent processes; thus, they are incapable of representing the changes and dynamics of geographic phenomena. Research efforts to extend GIS with the capabilities of handling spatiotemporal data have been ongoing since the 1980s.

The efforts of augmenting GIS with the capabilities of handling spatiotemporal data have been directed primarily at developing data models for time-dependent processes and phenomena. Similar to the object-based and field-based views of space, a discrete or a continuous view of time can be adopted in a temporal GIS design. The discrete time view uses two types of time objects to describe individually distinguishable events. A *time point* labels the existence of an event or the occurrence of a change, while a *time interval* denotes the duration of a certain status of a geographic entity. On the other hand, the continuous view treats time as a stage where the evolvments of various geographic events occur. This view is particularly important for tracing and studying the process of a geographic phenomenon in which changes take place gradually rather than abruptly.

Time-stamping presents a straightforward approach to adding temporal information to geographic entities. It has been widely used in various temporal GIS applications to integrate the geographic and temporal information of real-world entities. Depending on how a timestamp is applied to an entity, temporal GIS can represent its temporal information at different levels. A timestamp can be attached to a geographic layer (usually stored as a table in a relational database), and all geographic entities in the layer will share the same temporal information. A timestamp can be attached to every single geographic entity in a layer, and each entity will have its own temporal information. Also, multiple timestamps can be applied to different attributes of a geographic entity, and the entity will have attributes with different temporal characteristics. These time-stamping methods have been used in various temporal GIS models to represent changes of geographic entities and support relevant to spatiotemporal queries and analyses.

Another straightforward approach, the *snapshot model*, uses a collection of snapshots to represent the status change of geographic entities in an area. Each snapshot is taken at a specific time point; thus, all geographic entities in one snapshot share the same timestamp. The sequence of the snapshots then presents the change history of geographic entities in a particular area. In the late 1980s, Langran and Chrisman proposed a *space-time composite model* to record accumulated

changes in one single composite layer. A composite layer consists of a set of space-time composites that are derived from combining the geographic entities in multiple snapshots and represent homogeneous features sharing the same history and attributes. Each composite unit in the layer has its own timestamp. A historical state of a geographic entity can be constructed by combining several composite units associated to the entity according to their temporal sequence.

The snapshot model and the space-time composite model are capable of recoding spatiotemporal changes of geographic entities constituting a spatial data layer. However, neither of them can efficiently trace the change history of individual entities. In the 1990s, efforts were made to develop temporal GIS models that could explicitly maintain the lifelines of individual geographic entities. Special links are used to connect different states of entities that are stored in the consecutive snapshots or represented as a collection of space-time composite units. Therefore, a list of such links associated with a particular entity is able to capture the entity's lifeline, which may include various change events such as creation, transformation, disappearance, reappearance, destruction, and so on. As a special case, it is possible to model in temporal GIS the lifelines of moving objects (i.e., geographic entities with continuous motion but without changes of shape, such as human beings, vehicles, and wild animals). Since this type of entities can be simplified as point features, their trajectories, which record the history of their movements, can be conveniently represented as spatiotemporal lines in a temporal GIS environment.

The above approaches are mainly designed to deal with discrete changes. However, a continuous view of time is required for researchers to properly understand the dynamics of many geographic phenomena, such as the development of a weather system and an urban sprawl process. Thus, the ultimate goal of temporal GIS is to represent the dynamic process of geographic phenomena. This implies that a temporal GIS needs to go beyond simply recording the events and tracing the change history of geographic entities to developing the capability of capturing the driving mechanisms behind the displayed changes. Such an approach demands that researchers have a

clear understanding of the dynamic process behind the geographic phenomenon. Given the complexity of this approach, a temporal GIS application of this type usually focuses on a narrowly defined problem domain (e.g., meteorology) and uses mathematical models to simulate the process. Most existing efforts have been concentrating on loosely coupling a GIS framework with a separate system running a simulation model. So far, representing the dynamics of geographic processes remains a major research challenge in temporal GIS.

Temporal GIS also supports spatiotemporal reasoning that provides a theoretical foundation for analyzing the relationships and interactions among geographic entities. Researchers have been working on defining basic temporal relationships. For example, two time intervals can share various relationships such as before, equal, meet, during, overlap, start, and end. These temporal relationships can be combined with spatial relationships to represent rather complex spatiotemporal patterns of geographic entities. Various query and analysis functions have been developed in different temporal GIS applications to support the investigations of spatiotemporal relationships. These functions provide powerful tools for researchers to examine the dynamics and interactions of geographic entities in various research fields.

TEMPORAL RESOLUTION

Temporal resolution, well defined in the field of remote sensing, is one of four major resolutions that characterize a remote sensing system; the others are spectral, spatial, and radiometric resolutions. Temporal resolution is the length of time that has elapsed between measurements and captures the rate of data collection for a particular area. It can range from seconds to hours to days to years. Temporal resolution defines the minimum length of time over which an event can occur to be discernible in the database. For example, satellite images acquired for a forested landscape every year during the summer season will not capture phenological changes. Temporal resolution also plays an important role in geographic information science (GIScience) because all geographic data are defined with regard to spatial, temporal, and thematic dimensions.

In remote sensing, temporal resolution represents how often a remote sensing system records imagery for the same area. It is a measure of the length of time required for the sensor to pass over and return to exactly the same location, typically referred to as the revisit time. Remote sensing systems often differ with respect to temporal resolution. For example, Landsat 1 was able to acquire imagery of the same location every 18 days. Landsat 7 acquires imagery of the same location every 16 days. Therefore, Landsat 7 has greater temporal resolution. As the temporal resolution of a remote sensing sensor improves and the length of time between image acquisition declines, the number of images that can be acquired for the same area increases.

One of the most important aspects of a remote sensing system is its ability to collect imagery for the same location at multiple points in time. Comparing multitemporal imagery allows researchers to detect changes in spectral properties on the Earth's surface. Temporal resolution plays an important role in our ability to monitor these changes. For example, monitoring the growth of urban development would require a different temporal resolution (months to years) than monitoring the spread of a forest fire (hours to days). The temporal resolution of the remote sensing

system should reflect the changes occurring in the phenomenon under investigation.

In geographic information systems (GIS), temporal resolution refers to the length of time between map updates. For practical reasons, data in a GIS are measured and recorded in discrete temporal units, where each data layer displays the spatial distribution of the variable of interest at one point in time. When a set of data layers are acquired for a variable of interest over the same area at several time steps, the length of the time step between the layers represents the temporal resolution of the GIS database.

TERRAIN ANALYSIS

Generically, the term *terrain analysis* covers all processes that extract information from all kinds of terrain surface representation data. Such representations may include contour lines, profile lines, triangulated irregular networks, and square-grid digital elevation models (DEMs). The primary information extracted from terrain surface representations may be about local morphology or the characteristics of the entire catchment/watershed. Based on this primary information, the movements of materials controlled by gravity and the dynamics of energy

controlled by solar radiation over the land surface can be understood and described, and in turn, complex hydrological, geomorphological, pedological, and biological processes can be modeled. For this reason, terrain analysis has found applications in different fields, including geomorphology, soil science, hydrology, ecology, civil engineering, and environmental science.

The relationships between certain components in the natural system and terrain features have long been studied. A typical example of this type of relationship is the appearance of a “chain” of soils at different terrain positions along a slope. “Catena,” a concept proposed to refer to this soil-terrain pattern, became a cornerstone of the contemporary soil survey and mapping. However, only with the development of the contemporary digital technology did terrain analysis grow into a serious research field. Nowadays *terrain analysis* is almost a synonym of *digital terrain analysis* and is a significant aspect of the general spatial analysis that is based on geographical information science and technology. The most widely used terrain surface representation in digital terrain analysis is the square-grid DEM, due to its simplicity of format and easiness of algorithm implementation.

Terrain Attributes Characterizing Local Morphology

In digital terrain analysis, to measure the local morphological features at a given location, including slope gradient, slope aspect, and various types of curvatures, a conceptual procedure is to first represent the actual terrain surface in a mathematical way and then calculate morphological features as the derivatives of the mathematical surface. Specifically, slope gradient and slope aspect are calculated as the first-order derivatives of the surface, and the two most useful curvatures, profile curvature and planform curvature, are modeled as the second-order derivatives of the surface.

With a square-grid DEM, the primary approach to deriving derivatives from a discrete raster representation is the finite difference estimation. The basic idea of this method is to first fit a polynomial to a neighborhood defined by a group of cells (pixels) and then calculate the derivatives of the polynomial surface for the center location

of the neighborhood. The two most widely used polynomials for this purpose are the quadratic polynomial,

$$Z = \frac{1}{2}rx^2 + \frac{1}{2}ty^2 + sxy + px + qy + u,$$

and the Lagrange polynomial,

$$Z = ax^2y^2 + bx^2y + cxy^2 + \frac{1}{2}rx^2 + \frac{1}{2}ty^2 + sxy + px + qy + u.$$

In the above equations, Z is the elevation, x and y are geographical coordinates, and $a, b, \dots, u$ are coefficients whose values need to be derived from the actual terrain surface.

As an example, for a neighborhood typically defined by 3×3 cells, the equation for calculating the slope gradient (in angular degrees) for the center cell is as follows:

$$g = \arctan \sqrt{p^2 + q^2},$$

where p and q are calculated as follows:

$$p = (z_3 + z_6 + z_9 - z_1 - z_4 - z_7)/6w \text{ (under the quadratic polynomial)}$$

$$q = (z_1 + z_2 + z_3 - z_7 - z_8 - z_9)/6w \text{ (under the quadratic polynomial)}$$

$$p = (-z_4 + z_6)/2w \text{ (under the Lagrange polynomial)}$$

$$q = (z_2 - z_8)/2w \text{ (under the Lagrange polynomial)},$$

where $z_1, z_2, \dots, z_9$ are elevation values for the cells in the 3×3 neighborhood illustrated in Figure 1 (w is the length of one side of a cell).

Terrain Attributes Characterizing Catchment/Watershed

From a digital terrain surface representation, one can also derive information that characterizes the entire catchment/watershed. This information typically includes descriptive statistics of the watershed (e.g., minimum and maximum elevations of the watershed) and attributes regarding water flows.

Most attributes regarding water flows are based on the information about local flow direction,

Figure 1 A typical 3×3 neighborhood defined over a square-grid digital elevation model

Source: Author.

which is derived from differences between nearby elevations. The most common method for calculating flow direction is the D8 algorithm, which assumes that the water in the center cell of a neighborhood flows only into one of its eight neighboring cells—that is, in the direction of the steepest descent. Based on the flow direction calculated in this way, information about flow path, slope length, upper-stream drainage area (flow accumulation), and watershed boundary can be derived.

Combining flow accumulation and slope gradient leads to an attribute that effectively characterizes the local moisture condition. This attribute is called wetness index or sometimes compound topographic index, which is calculated as follows:

$$w = \ln\left(\frac{A}{\tan g}\right),$$

where A is the flow accumulation and g is the slope gradient measured in degrees.

Ongoing Research

One challenging issue in terrain analysis is to automatically recognize the predefined terrain positions from a digital terrain surface representation, such as a square-grid DEM. This type of

technique is useful because much of the existing knowledge in a field-based soil survey and mapping is associated with terrain positions. This recognition requires an integration of local morphological information and contextual information. Fuzzy logic has also been introduced to this problem to improve the accuracy and precision of the terrain position representation.

Another major research topic in terrain analysis is the impact of the resolution of the input DEM on the resulting terrain attribute values. This research is driven by the increasing diversity of data sources (particularly from remote sensing) and the increasing availability of high-spatial-resolution data. Understanding the advantages, disadvantages, and uncertainties associated with these data and their suitability for different applications is the prerequisite to the proper and full utilization of the data.

TERRITORY

Territory is an important concept for understanding politics and social behavior. Although unsettled etymologically, the term *territory* is usually taken as a derivative of the Latin *terra* (land); however, it has also been suggested that it is derived from the Latin *terrere* (to frighten), indicating that territory is a place that frightens people. This dual meaning is key to understanding territory. Most theories of the state point to territory, in combination with sovereignty and population, as the defining features of the modern state. Yet in a broader context, territory refers to the space occupied, or claimed, by a group of social beings. Essentially, territory indicates a bounded social space of dominance, identity, or jurisdiction.

Territory is a heavily contested concept across the social sciences, where there is little agreement on what territory is or what it means. Therefore, rather than presenting a narrow, unambiguous version of what territory is, this entry describes some basic understandings of territory and presents some of the key considerations surrounding territory, with special emphasis on political territory.

Three Key Functions of Territory

There are three dominant ways of understanding territory:

1. It refers to the natural habitat of a group of people or animals. In zoology, it refers to an area occupied by an animal or a group of animals, which they defend against others of their own kind.

2. It represents a social space that is constituted as a result of the behavior of a group of people, for example, when the supporters of one football team occupy a part of a section of a stadium, they create an area designated for them, where supporters of the other team are not welcome.
3. It denotes an area over which a polity claims dominion. This could be the area surrounding a city-state in early modern Italy or a modern state territory as that of contemporary France. In international law, territory plays an essential role in defining nation-states as legal members of the international community.

Common to these three understandings is the creation of a space from where something, or somebody, else is potentially excluded.

Thing Versus Process

It is impossible to understand territory without a reference to land; however, the physical character of territory is often overestimated. While territory is constituted through the demarcation of a physical space, it is the delimitation and character of this space that give territory its characteristics. The existence of boundaries is never a natural phenomenon; even if mountain ranges or seas can make it impractical for people to move across them, boundaries are always a relational, and hence socially created, phenomenon. One should be careful, therefore, about treating territory simply as a physical object. Rather, territory should be understood in terms of the social relations that produce territory and are affected by territory. For example, it was the development of cartography that provided the spatial knowledge necessary for states to precisely define and agree on the boundaries vis-à-vis each other. This change, in turn, facilitated the development of distinct territorial societies. Without these developments in geographic knowledge and technologies, territory is unlikely to have played the central role that it plays in current affairs. Therefore, to understand what territory is, and how territory is created, we need to look at the historical social processes involved. Such processes are usually described as territoriality or territorial behavior.

Territorial Behavior

As a general concept, territorial behavior describes actions that aim to create a bound social space within which one dominates, and thus excludes others. This can refer to the territory of animals or the erection of a fence to mark off one's property. Understood in this way, territory is a central aspect of any social order referring to the distribution of space, as well as a strategy to create space as one's own. When an urban gang competes with another gang to control a part of a city where it seeks to control drug trade and other illegal activities, it constitutes a territory where members of the gang dominate and from which others are frightened off. In extreme cases, such as the clashes between gangs and paramilitary troops in urban slum areas in Brazil in the early 2000s, the gangs openly challenged the sovereign authority of the state and created territories where authority was disputed. Conflicts between groups of people, such as the divisions in Northern Ireland, can also result in territorial divisions, where sections of the capital, Belfast, have been divided into strict zones for Protestants and Catholics. These zones would not be officially sanctioned by state authority but would be recognized in, and maintained by, the everyday patterns of behavior of the population. Whereas these examples of territoriality produce shifting and maybe vaguely bounded territorial spaces, the political territories of states, appear as more static and settled.

Political History

International politics is based on what is called a sovereign territorial order. This means that the international system is based on sovereign territorial states that recognize each other as legal subjects of international law. Without territory, a state cannot be a legal entity. Territory plays the role of dividing the legal jurisdictions among states into distinct sovereign spheres, and it is, therefore, territory that serves as the foundation of differentiating different sovereign entities as states. Historically, this system is accredited to the peace treaties of Westphalia, officially marking the end of the Thirty Years War in Europe (1618–1648) and initiating a new system in which nation-states rather than feudal empires played the dominant role in continental

(and later, global) politics. These events signaled the spatialization of politics and replaced the system of jurisdictional sovereignty that had characterized medieval politics in Europe. Jurisdictional sovereignty represented a relationship between the sovereign ruler and his or her subjects. As such, it was primarily a hierarchy of personal relationships that decided the extent of the territory over which a ruler could claim dominion. In contrast, the spatialization of politics meant that sovereignty began to refer to a specific area of geographical space; and whoever was living within this area would automatically be considered to be subjects of the sovereign ruler. In sum, the territorialization, or spatialization, of politics points to a transition in the relationship of the sovereignty of a ruler from personal relations to a specifically defined space. This process started in the 15th century and became a defining feature of European politics over the following centuries (Figure 1). Following European colonization of the rest of the world, sovereign territoriality became the dominant way of organizing international relations, and following World War II, sovereign equality based on territoriality was adopted as the main principle of the UN charter.

National Identity

Most theories of national identity and expressions of nationalist ideology stress the link of a nation to a specific territory or homeland. Narratives about the special character of a particular land—its beautiful valleys, forests, and so on—serve to link a particular group of people to a particular land. In theories of national identity, it is common to distinguish between articulations of identity associated with blood lineages (where the collective identity is constituted through kinship-like relations) and articulations of identity associated with territory or the land (where residence within a particular territory is constitutive of the collective identity). The former is associated with the historical example of German national identity, and the latter with France. Regardless of whether territory defines the extent of the collective identity, however, the notion of a homeland is crucial. What is significant is the way in which the territory acquires the role of a home for a particular collective. This discourse of the territory as home is strengthened by the feeling of familiarity that

Figure 1 Cartographic representations, such as Blaeu's map of Europe from the mid 17th century, contributed to the perception of a world divided into neatly bounded territories.

Source: Public domain.

most people have when they return from travel and is associated with being back in a particular territory. In that respect, it is through the discourse on national identity that a population and a territory are tied together into a unit.

Territorial Conflict

Territory has often been a source of conflict and war, caused by competition over natural resources, by a general competition for access to land, or by competing notions of national identity claiming the same area as a core aspect of a particular nation. In legal terms, there is a tension in international politics in that territorial sovereignty is expressed through the norm of territorial integrity

that seeks to maintain the territories of current states intact, but at the same time, territorial sovereignty is legitimized through a claim to national identity. When a recognized state territory contains what is perceived to be more than one nation, it is logically impossible to sustain both the norm of national self-determination and the notion of territorial integrity. This was clear during the 1990s, when the former Yugoslav Republic was split up into smaller states after a series of bloody wars justified with reference to national and ethnic cleavages. Territorial conflict or competition can also take place in a more peaceful way. In recent years, the Arctic region has attracted increasing attention from the Arctic countries, all of which try to claim large areas of the Arctic

seabed. This is done with reference to the UN Convention on the Law of the Sea (UNCLOS) from 1982, which specifies the conditions under which a nation can expand its domain at sea. The countries involved pursue territorial enlargement to get control over the natural resources that might be found there.

Network Versus Territory

In recent years, the significance of territory has been challenged by new approaches to social science. The end of the Cold War and the rise of globalization have led many to believe that territory is becoming less significant. Especially, social constructivist and postcolonial writings have emphasized new “spatialities” coming to play a more significant role and, in doing so, undermining the preeminence of territory. With the advance of communication technology in particular, economic and social transactions can be carried out in an instant across long distances, and it has been highlighted how global networks cut across territorial boundaries and thereby undermine the capacity of the state to exercise sovereign authority within its territory. The main contribution of these writings has been to critically investigate the history and status of territory. By emphasizing the historical development of current territories, and especially contrasting these with non-Western experiences of the territory and spatial behavior, they have shown a range of alternatives to global politics based on a territorial order. For example, poststructuralist studies often stress the existence of alternatives to territorial societies by investigating nomadic traditions and behavior, which they describe as another way of organizing social space. These writings have provided an important contribution by pointing to the limits of viewing the social world from a purely territorial perspective. While it would be a folly to claim, generally, that territory as such no longer matters, it is important to keep in mind that various social practices, such as economic interaction, tend to follow a nonterritorial logic. A useful way to approach this tension is to think about territory and networks as two different social spatialities that often contradict each other while they necessarily coexist.

TERRORISM, GEOGRAPHY OF

The geography of terrorism refers to the spatial and locational characteristics of terrorist incidents, including the global and regional patterns of terrorism, the physical places where attacks occur, the location and activities of the human victims of attacks, the spatial and operational characteristics of attack locations, the types of land use commonly subject to terrorist attacks, the ways in which terrorist actors intersect in time and space with the intended victims, and, most generally, the extent to which the characteristics of places and the human activities occurring there interact with political, ethnic, racial, social, religious, or other ideological motivations and attack methods to produce terrorism.

The geography of terrorism is complex and multidimensional. It includes a political geography of the nation-states involved in the sociospatial control of various territories and the official public responses to the incidents of terrorist violence within those territories. Terrorism has a temporal geography, in which tribal or communal hatreds and vengeance propel cycles of reciprocal

political violence within a society over time. Terrorism has an urban and rural human geography, in which the spatial arrangements of ethnic, religious, and racial groups set the stage for terrorist violence. Terrorist violence has a military geography, involving the conquest and control of space and the capture and maintenance of territory.

Definitions of Terrorism

Definitions of terrorism abound. Terrorism is viewed in this entry as the use of violence by individuals, substate groups, agents of the state, and state authority against innocent victims to achieve political, ethnic, racial, religious, or other ideological objectives. Terrorism can be a broad strategy as well as an individualized tactic used in sociopolitical conflict, practiced by nation-states and substate actors alike. The sociologist Donald Black defines pure terrorism as a form of social control and collective self-help among groups addressing perceived problems—one group wages collective violence on others to get something done or to stop something. Terrorism is also considered to be a tactic of asymmetric warfare.

Geographical Components of Terrorism

Every terrorist incident occurs in a physical place in which four necessary elements of terrorism come together: (1) the perpetrator of terroristic violence, (2) the victims of violence, (3) the types of violence (methods and weapons), and (4) the ideological motivations that transform ordinary criminal violence into terrorism. The interactions among terrorists, victims, methods, motivations, and places of attacks produce several geographical dimensions of terrorism.

Spatial Strategy of Terrorist Violence

Terrorist behavior has a spatial component when violence driven by political, ethnic, sectarian, or religious motives is perpetrated to control, change, or eliminate the activities occurring within an area or the people occupying that area. Terrorist violence is instigated to (a) drive out the occupants of a particular place, (b) keep other parties away from an area, or (c) stop certain activities from occurring in an area. Alongside

these motivations is a desire to create a climate of fear through random violence that sends a message that no place is safe and that the innocent will be targeted to accomplish the terrorists' objectives. Ethno-nationalist, state terror, and genocidal campaigns commonly include explicit spatial strategies to stop the performance of human activities in a space, drive people out of certain spaces, or simply eradicate them.

The geography of terrorism involves a broader conception of victimization in which the places of terrorist incidents—as well as the humans in those spaces—are an integral part of attacks and their ideological messages. Assaults on government buildings, diplomatic facilities, public markets, clinics, or pristine natural spaces all send direct and indirect messages to intended audiences, based on the characteristics of the places attacked and the human activities they host. The places attacked are part of an informational strategy of terrorism and often reflect multiple layers of meaning. At a minimum, terroristic violence persuades citizens that the targeted spaces are not safe.

Treatment and Control of Space in Terrorism

Terrorism can have clear geographical motivations. Land control is at the core of the Palestinian-Israeli struggle. The Irish Republican Army (IRA) used terrorism to dislodge Britain's occupation of Northern Ireland. Controlling land was the primary motivation in Sendero Luminoso's violence in Peru, strategically as an example of Maoist guerrilla warfare and tactically as a way of gaining control over coca production. Colombia's terrorist violence stems from the agricultural sources, production locations, and transport of illicit drugs. The Tamil Tigers use terror tactics to capture and control land in Northern Sri Lanka. The ETA (*Euskadi Ta Askatasuna* [Basque Homeland and Freedom]) in Spain uses terror to struggle for sovereign status for the Basque land in the Northern Iberian peninsula. In the past 30 years, radical Islam's interest in the holy sites of Mecca and Medina has produced major terrorist incidents. In Rwanda in 1993 to 1994, the Hutu used mass murder to erase the Tutsi from Rwandan territory. The Sudanese government depopulated

New York City, September 25, 2001: Fragments of the World Trade Center façade that remained after the attacks on the 110-story structures that once dominated the skyline of lower Manhattan.

Source: Mike Rieger/FEMA News Photo.

the indigenous population of Western Darfur using terror tactics between 2003 and 2008. In all these ways, land and spatial control can be the strategic focus of terrorism.

Location of Terrorist Acts Among Political Jurisdictions

The global geography of terrorism begins with the spatial distribution of terrorist incidents among countries. Individualized terrorist attacks occur, and over time, clusters of incidents appear among sovereign states. Spatiotemporal clusters of terrorism among countries are built on the spatial and sociopolitical context of each country, as defined

by its longer histories of political, social, ethnic, or religious conflicts, including not only internal ones but also conflicts with other countries. Terrorism is produced by different actors—it has been executed very effectively by nation-states, by organized and disorganized substate groups, and by grassroots “leaderless” resistance networks. Any of these groups can wage extended campaigns of terror. Furthermore, terrorist groups originate from selected countries and can show specific spatial allegiance to certain areas. Depending on their potency and motivations, groups sometimes wage terror campaigns in other countries or work covertly with public authority when state-sponsored terrorism is involved.

Location and Situational Characteristics of Terrorist Acts

At a more resolved spatial scale, regional differences in terrorist incidence rates are important. Black (2004) suggests that terrorism arises in places where sociodemographic structures result in (a) long social distances between people in terms of their ethnicity, religion, social class, corporate status, or hierarchical authority and (b) short physical distances between people who are socially distant—that is, there is a large social distance between people who live in close proximity to one another. Terrorist violence frequently generates mass casualties, so population density is an important part of terrorist targeting strategies, creating higher urban risk profiles. Within countries, selected cities and localized regions become repeat hosts of terrorist incidents. Acts of terrorism also occur within a set of local operating environments (e.g., an airport, a public park, an office, a government facility). This means that certain land use classifications become more or less attractive targets. For example, land zoned for public transportation corridors has been the scene of devastating terror attacks over time. Countries hosting “mega-events” (e.g., Olympics, Super Bowl, World Cup) have higher risks of terror attacks during such events.

At a basic level, the target of terror attacks sets up the geography of terrorism. Places targeted are rarely random but are chosen for tactical or symbolic reasons. Physical places are often the targets of terrorist attacks because they host some activity. Medical facilities, timber companies, airline counters, dwellings, and places of business have all been sites of terrorist crimes, from minor vandalism through catastrophic destruction. Public markets, restaurants, meeting halls, hotels, office spaces, transport facilities, and resorts are targets of terrorist violence. Sometimes, the place is a more important targeting dimension, while at other times the functions performed in that space are more important. A terrorist incident can target a women’s birth control clinic, the observation deck of a skyscraper, a parking garage, or an airport ticket counter. Terrorism targets locations that have functional or operational characteristics (e.g., a place where abortions are performed, where Hindus worship, where foreign tourists

congregate, or where international business is conducted).

Another geographical component of terrorism comprises the situational aspects of places where terror attacks occur. A detailed analysis of terrorist incidents reveals a wide array of settings. Suicide bombings on public transportation were common in the Israeli-Palestinian conflict and spread to London in 2005. Bombings in restaurants, resorts, and hotels target innocent “occupiers of space” at a particular time. Targeted assassinations occur in residential areas, striking victims in their homes. Firebombings are used in exurban locales by environmental extremists and insurgent groups. Terrorism is often defined based on the characteristics of the attack victims who came together and engaged in routine activities in common places (e.g., a wedding party, a dinner, a shopping center, a station, an airport, or a school).

Terrorist incidents are sometimes designed around the locational and operating characteristics of a target. The Earth Liberation Front firebombs automobile dealers selling Hummers to protest against gas-guzzlers or uses arson to burn partially built houses in undeveloped areas. Mexican narco-terrorists murder an off-duty police official at his residence to demonstrate people’s vulnerability in their homes. The 2006 Mumbai train bombings by a grassroots Islamic group targeted first-class commuters during the evening rush hour.

The targets of terrorism can be comparatively undefended, more accessible to terrorist actors, or difficult to guard and protect. Residential sites and public spaces are relatively undefended. But fortifying the target does not necessarily dissuade attacks. Surprisingly, well-defended places are frequent targets. The multitude of city spaces exhibits higher landscapes of risk. Certain kinds of land use (e.g., public spaces, public transport facilities) are more likely to be the site of terrorism incidents.

At the closest spatial scale where terrorist actors or agents cross paths with victims, terrorism consists of one or more sequential crimes, such as kidnapping, assault, attempted murder, or murder. Each crime is implemented using a method and one or more weapons. The crimes occur together in time and space. The methods and weapons used determine whether the terrorist physically crosses

paths with the victims or instead leaves a device that delivers the attack. The distance from terrorist to victim can be near or far depending on the method-weapon combination. Using a scoped rifle to close the distance between the killer and the victim keeps assassins farther from their victims, as do remotely detonated bombs. At other times, suicide attackers get close to victims. Transportation and communications technologies help create spatial connections between victims and terrorists. Cellular technology and the Internet help coordinate attacks from longer distances. Terrorist groups use technologies (e.g., letter bombs, firearms, computers, airplanes, trains, buses, car bombs, improvised explosive devices) to deliver attacks, which enable terrorist agents to escape, fight it out, or die at the attack site.

When terrorist actors use biological or chemical weapons, or remote detonations of explosives, a slightly different geography develops. Attackers and victims may not come into direct contact, and often the results are not seen until later, after the terrorist actors leave the scene. Letters and parcels bearing viral or biological agents or explosives can use postal systems to reduce the distance between the victims and the terrorists. The U.S. anthrax terrorists in 2001 were probably nowhere near the victims. In contrast, the 1995 Tokyo subway attacks required Aum Shinrikyo members to intermingle with victims in subway cars prior to piercing the bags of sarin and leaving. The 1993 World Trade Center and the 2004 Madrid train bombings used timed detonators that maintained separation between the terrorists and their victims.

Research Questions

The geographical components of terrorism are far-reaching and suggest various avenues for further research. Key questions include the following:

1. What spatial strategies are embedded in terrorist campaigns?
2. Which countries host large rates of terrorist violence, when, and why?
3. Where within a country do terror attacks occur?
4. What land uses and human activities are under way at the places targeted by terrorist violence?

5. How do terrorist actors or agents intersect the personal space of victims?
6. How do terrorists distribute violent incidents across their activity areas?
7. What does the risk profile of a region look like?
8. How do public responses to terror affect people's movement through space?

TEXT/TEXTUALITY

There is no clear consensus as to what constitutes a text or how the term should be defined. Instead, the term falls victim to a wide array of interpretations and applications across and within

various disciplines; however, it is often associated with the pioneering work of Roland Barthes and other literary theorists and cultural anthropologists such as Paul Ricoeur, Clifford Geertz, James Clifford, George Marcus, and Stephen Tyler. Here, text is regarded as a sociocultural product and/or process and is expanded from its traditionally narrow definition of being a mere printed medium to include things as wide ranging as paintings, photographs, maps, electronic media, landscapes, as well as economic, political, and social institutions.

A text, in the broadest sense of the word, can be regarded as a configuration of signs that is coherently interpretable by some community of users. Implicit in the definition is the view that something can only qualify as a text if it is void of anonymity, randomness, and illogic. Hanks (1989), for instance, distinguishes the senseless cacophony of a crowded street from the sound exchange of words between two mutually oriented interactants, or the noise of rush hour as opposed to the concerted dissonance of a dramatic passage in a musical score. Texts are therefore innately communicative and are part of an ongoing discourse produced, received, and interpreted by various social actors and agents.

The reading of a text occurs through its textuality. A text is replete insofar as it is grounded in a locally defined social context. To understand a text and make it semantically whole, the reader has to draw on a variety of background information or seek to understand the particular context that gave rise to such text. Even the most rigorous of linguists with their emphasis on textual form and content make reference to a text's connection with the sociocultural world. Textuality then refers to the attributes that distinguish the text as an object of enquiry. Texts are produced and understood in terms of the broader sociocultural context in which they arise. If read in isolation from the broader social matrix of which it is inherently a part, a text becomes incomplete and indeterminate.

The term *intertextuality* is also linked to the use of "text" as a concept. Implicit in this is the view that all accounts of the world are highly mediated by preexisting notions and theories. Places are intertextual in that they are shaped by previous texts and practices that are deeply

inscribed in their landscapes and institutions. In short, texts shape, and are in turn shaped by, other texts. Therefore, meaning is produced from text to text rather than in and of the texts themselves.

The Discourse on Text

The discourse as to what constitutes a text, and in extension its textuality, has been a long-standing and ongoing one. There are indeed many approaches to the study of text. Approaches to textual analysis can be differentiated according to the scope and extent to which text is seen as an object of enquiry. For a structuralist, texts are seen as products of an ongoing hegemonic discourse. Much of the initial work on texts in structuralism was carried out by Roland Barthes, who believed that the world was made up of signs. By studying these signs, Barthes believed that one could uncover the complexities and the instability that underlie our everyday life. Accordingly, landscapes were perceived as being produced and shaped consciously to represent a particular set of values and belief systems. Landscapes were therefore found to be unnatural and highly ideological and political. In one of his most famous essays "The Blue Guide," Barthes (1986) critiqued the widely used *Hachette World Travel Guide* as being an instrument of Western cultural manipulation. Barthes illustrated how, by showcasing a limited range of landscape features, the travel guide plays into Western constructions of place, thus ignoring the familiar (Western) and romanticizing that which is deemed as unfamiliar (the Orient). In fact, Barthes described the travel guide as an "agent of blindness," one that conceals non-Western realities.

Poststructuralists, on the other hand, challenge the structuralist notion that texts are coherent and self-contained. Instead, advocates of poststructuralism posit that texts are innately contradictory and indeterminate. Poststructuralists therefore shift their focus away from the text itself (as a bounded linguistic artifact) to the interaction between reader, text, and author. The consequence of this change is the expansion of the notion of text to include even social life.

This expanded notion of texts also has its roots in postmodernism. The postmodern view sees

texts as being constitutive of reality rather than mimicking it. For postmodernists, the world is like a text encoded with meaning. Ricoeur, for instance, posits that social life has characteristics strikingly similar to those of a written discourse. For Ricoeur, social life, like text, is detached from the intentions of its original authors, is inherently unstable, and possesses a certain amount of objective fixity. Additionally, social life has an importance beyond the initial context for which it was constructed—again, like that of a written text. Similarly, Clifford Geertz looks at cultures as texts; for him, culture can be “read” by an ethnographer as one might read a book. He extends his point by claiming that this practice is not only academic in its orientation but also one that everyone practices.

Text, Textuality, and Geography

The bulk of the literature on text and textuality has been confined to a few disciplines—literary studies, linguistics, and anthropology in particular. Most of the initial work focused on issues relating to the organization, production, and interpretation of texts. Throughout the 20th century, competing methods of textual analysis were put forward. Advocates of structuralism have focused on semiotics or text as signs, while post-structuralists have looked at text as being constitutive of larger and more dynamic discourses. The latter mostly adopts a Foucauldian interpretation of text. Here, discourses are seen as connected to knowledge, identity, and power. Society is seen as filled with multiple discourses that are representative of various interest groups. Texts either reflect or shape these multiple and sometimes competing discourses. Over the past few decades, these textual methods of analysis have attracted much attention and interest in the social sciences in general and geography in particular.

It was not until the 1980s and 1990s (during the rise of social and cultural theory in geography) that geographers became interested in textual analysis. This cultural turn saw the promotion of a hermeneutic approach to the study of place and the politics of representation. Most of these studies have focused on landscapes, cultural landscapes in particular. For geographers (new cultural geographers especially), texts represent a

valid way of interpreting landscapes. Implicit in this notion is that landscapes are themselves encoded with messages and can therefore be “read” and decoded as texts. Geographers are interested in the way places themselves encapsulate and communicate cultural identity and how these places in turn shape our own perceptions and identities as social beings. People’s interactions with their surroundings are therefore viewed as interactive and dynamic rather than one-dimensional and static. Landscapes are constantly “written” and inscribed with meanings. These meanings can then be “read” or interpreted as signs about the particular values, identity, beliefs, and practices evocative of that particular landscape, place, space, or era. However, to read these signs, one must understand the language in which it was written—in other words, one has to become familiar with the text’s textuality.

Barnes and Duncan’s (1992) *Writing Worlds* illustrates the many ways geographers have used concepts such as text, discourse, and metaphor to explore the dynamics of power in the representation of landscape. Though the landscape representations explored by the authors in the volume varied considerably (from travelers’ writings to propaganda maps), a common theme running throughout the book was that all sociocultural products and practices, including landscapes, social action, paintings, maps, and even language, are susceptible to textual interpretation. McGreevy (1992) showed how written accounts of the Niagara Falls—dating back to the late 19th century—were informed by the metaphor of death. He went a step further to illustrate how this metaphor of death had crept out of the written texts of the area into the very landscape humans created around the Niagara (evident especially in the many acts of suicide carried out in the area). Likewise, Daniels (1990) used a watercolor depiction of Leeds painted by J. M. W. Turner in 1816 to show how even works of art are themselves inscribed with meaning and can be “read” as text. Daniel showed how the painting addressed both the features of Leeds’ industrialization as well as the intellectual and political psyche of Turner and his time.

Another study worthy of mention is that of Denis Cosgrove (1998), who applied social and cultural theory to the study of landscapes.

According to him, landscapes are constructed and shaped by sociocultural and political processes and thus represent a “way of seeing.” Ways of seeing are ideological and signify the way in which the dominant class in a society represents itself and its property. In short, landscapes are both constituted by and constitutive of social power relations.

Recent research in subjects such as sociology, anthropology, and human geography has built on these past notions of text—though not explicitly—in exploring issues relating to the politics of place, identity and culture, place making, place/destination marketing, transnationalism, and even graffiti. Studies have shown, for instance, how various media texts (including the Internet, travel blogs, online advertisements, and other promotional literature for instance) have helped to either reproduce stereotypes or challenge dominant images of places. Erjavec (2001) showed how the theme and form of news reports worked to reinforce and legitimize discrimination against the Roma in Slovenia during the 1990s. Morgan and Pritchard (2002) also revealed how destination-branding strategies helped shape Wales’s tourism efforts. Based on their analysis of the marketing campaigns and promotional literature of the Wales Tourist Board in particular, the two concluded that the influence of both repressive and liberating historical, political, and cultural discourses was seen in the way Wales marketed itself as a tourist destination. Both examples—though different in their focus—speak to the relationship between texts, identity politics, and place representation.

Even more recently, Mains (2008) has shown how Latin American transnational identities are inscribed in both the cultural and the physical landscapes around the U.S./Mexico border. In looking at the movements or exchange of music and architecture between both sides of the border, she illustrates how cultural identities shape the way places are constructed and represented. For instance, in both Northern Mexico and California, Mexican hip-hop, *ranchero* music, and U.S. rock music dominate. These musical forms are often bilingual, thus indicative of the influence of what can be termed *transnational or border identities*. Similarly, Mains argues that an examination of the built environment of cities

such as Los Angeles or Tijuana will show the influence of Spanish colonial plazas and gardens, indigenous adobe materials, as well as modernist office buildings—again reminiscent of a transnational culture but also indicative of the ways in which cultural identities are sometimes manifested in the physical landscape and in turn mapped onto space. In short, the U.S./Mexico border and its associated cultural and physical landscapes can be read as texts, as they embody the interconnectedness with people and places throughout the Americas and have given rise to, and become increasingly shaped by, a number of distinct and competing discourses on mobility, immigration and legality, and transnational identities to name some.

As mentioned before, even graffiti can be looked at as texts and can be used to understand relations and contestations of power in urban space. Here, graffiti are defined as a sort of text that adopts a historically and culturally grounded interpretation of some aspect of the world, shaped by human personalities and actions. Graffiti not only alter or edit the text of the cityscape but also form an independent body of texts that refer to each other as well as to the “canvas” of the city on which they are literally inscribed. Graffiti thus represent a written and visual aspect of language, with their own semiotics of action, that if read properly can uncover the cultural politics of place, as well as various geographies of power and identity.

There are, however, a number of problems associated with the use of text and, in extension, textuality. A major one relates to the issue of representation. There are important epistemological and ethical issues surrounding the notion of representation and its implications for textual analysis. Duncan (2000) points out two such concerns. The first refers to the issue of the translatability of cultural difference, and the second refers to the ethics of speaking for others. The signs that are embedded in a landscape may have different meanings for those who produce them and for those who interpret them. As such, great care has to be taken when interpreting these meanings. Researchers have to be mindful of their own biases as well.

TEXTILE INDUSTRY

The textile industry encompasses a sequence of production processes that transform raw materials into finished textiles and clothing products. Production in these sectors is shaped by two fundamental characteristics. First, cloth is relatively malleable and fragile, so commodity manufacturing in these industries has resisted automation and remained labor-intensive. Second, because the industry's production processes are divisible and able to be separated or vertically disintegrated into sequential stages, firms are able to locate each stage of production at the most advantageous site. As a result, the sector has developed a globalized organizational structure. Figure 1 provides a simplified view of the textiles production sequence.

The raw materials used to make textiles include natural fibers, human-made fibers, and combinations of the two. Natural fibers include cotton, wool, silk, flax, and hemp. Human-made or synthetic fibers can be obtained from processing petrochemicals (nylon and polyester) or made from

Figure 1 The textile industries

Source: Adapted from Dicken, P. (2004). *Global shift: The internationalization of economic activity* (5th ed., p. 234, fig. 8.1). London: Paul Chapman.

cellulose, which is derived from wood or cotton (rayon and viscose). Although the actual processes differ depending on the type of fiber, textile production involves spinning thread, weaving or knitting it into fabric, and then dyeing and finishing the fabric in different ways, depending on the intended end use. Technological advances in fiber manufacturing have generated a highly automated and capital-intensive subsector. In addition, a vibrant research sector is developing patentable new fibers that combine natural and synthetic materials for a range of high-technology applications (e.g., the carbon-coated textiles used in the aerospace industry).

Textiles have a wide range of industrial, household, and personal uses. They are the principal material in ropes, sacks, canvases, and fiberglass and have a wide range of industry uses (e.g., in filters and the rollers used in printing mills). Textiles are found in home and office furniture, carpets, curtains, bedding, as well as in the interiors of transport vehicles. Nonetheless, about 40% of textiles are used as inputs to clothing production.

Clothing production involves designing garments; making patterns; cutting cloth; sewing the cloth into garments; adding buttons, zippers, and other accessories; and then checking and packaging the final product. Basic clothing production (i.e., cutting and sewing pieces of cloth) does not require advanced skills, complex equipment, advanced technologies, or large capital investments. Clothing

manufacture is therefore characterized by what economists call low barriers to entry and exit, meaning that firms can easily come into or drop out of the industry. As a consequence, the sector has historically been volatile and mobile, changing rapidly in response to the vagaries of the business cycle and shifting its production locations in response to regulatory changes and interregional wage differences.

The sector exemplifies five key theoretical themes in economic geography and development studies: (1) the geopolitics of economic globalization, (2) the tensions between globalized production networks and localized industrial districts, (3) the internationalization of struggles over labor rights, (4) the flexibilization of the labor process, and (5) the contemporary repositioning of “cultural” industries.

Textiles in International Trade and Development

The textiles industries were one of the first sectors to develop globalized production structures and are now the world’s most traded commodities after agricultural goods. Textiles industries are the world’s most regulated industries and are unusually sensitive to policy change.

Textiles have played an important role in international trade and national development. Clothing production’s low entry costs, accessible technologies, and modest skill demands make it

the logical choice of industry to “kick start” national development strategies. Numerous industrializing countries have sought to exploit their comparative advantage in abundant and cheap labor by establishing clothing and textiles production industries. Accordingly, the sector has been the centerpiece of export-oriented industrialization strategies in Japan, Korea, and Hong Kong after World War II, in Asia’s newly industrializing economies (NIEs) in the 1980s, and in China since the 1990s.

Clothing and textiles production in the developing countries often occurs in export processing zones set up to attract foreign direct investment. These zones offer a range of incentives to capital, typically low wages, low infrastructure costs, tax holidays, and cheap and nonunionized labor. In the 1970s and 1980s, the growth of clothing production in less developed countries was fuelled by the relocation of production by Western firms seeking to reduce their labor costs or to escape the unionized workforces of factories in their home economies. Thus, the sector has been the archetypal example of the process of relocation of jobs from the developed to the developing world, a process known as the new international division of labor.

In the post–World War II era, Western governments imposed restrictions on textiles and clothing imports with the aim of protecting jobs in their home economies. The most important of these interventions was the 1974 Multi-Fibre Arrangement (MFA), which was an exception to the General Agreement on Tariffs and Trade (GATT), which allowed high-wage countries to impose import quotas that limited textile imports from low-wage countries. The developing countries viewed the MFA as an impediment to their economic development. At the Uruguay Round of GATT negotiations, member nations agreed to discontinue the MFA and bring clothing trade in line with the rules governing trade in other manufacturing sectors. Between 1995 and 2005, therefore, a transitional Agreement on Textiles and Clothing (ATC) was put in place to gradually phase out the sector’s quota restrictions.

Trade liberalization generated major shifts in the global configurations of textiles and clothing

industries. Figures 2 and 3 show the principal exporting countries’ shares of world textiles and the clothing export trade for the years 2000 and 2006. Both sets of figures highlight the rapid growth of Chinese exports. India, Turkey, and Pakistan have also benefited from recent regulatory reforms. In textiles, the losers in this process have been South Korea, Taipei, Hong Kong, and the United States. In clothing, Mexico, the United States, Hong Kong, and many small countries with low export volumes have lost market share. Hong Kong’s position as a reexport platform is faltering as Western firms increasingly source products directly from China.

Because trade liberalization has removed the advantage previously enjoyed by smaller developing countries (whose textiles exports were not restricted by MFA quotas), production now appears to be concentrating in and around specialized garment production regions. Both the United States and the European Union negotiated new agreements with China in late 2005 to slow the growth of imports into their markets.

The Commodity Chain Perspective

Commodity chain perspectives highlight the institutional relationships that shape trade flows. They view aggregate trends in textile production and exporting as the outcome of transnational subcontracting arrangements between firms. In textiles, these chains of interconnected firms are usually coordinated by large brand-owning core firms based in high-wage nations. Gereffi has called this form of industrial organization a “buyer-led” commodity chain (Figure 4). The commodity chain worldview assumes that power and profit accrues to core firms located close to consumer markets.

In reality, however, the structure of relationships between firms is complexly contingent on a host of factors, including the costs of production in different places; worker productivity relative to wage levels; the uneven landscapes of global and national regulation; the fashion sensitivity of particular products (which determines the “turnaround” time of the product cycle); transport costs; geopolitical conditions; the relative locations of designers, textile inputs,

Figure 2 Leading textile-exporting countries

Source: Created from data in World Trade Organization, *International Trade Statistics*, 2007, Table 11.58: “Leading exporters and importers of textiles, 2006.”

accessories, factories, and markets; and, importantly, the power relations among suppliers, intermediaries, and buyer firms. These factors tend to create a product-specific hierarchy in which less complex, high-volume garments are made in low-wage countries while low-volume, fashion-oriented garments are made closer to their final consumption market.

National and global trade regulations are an important influence on the configurations of global production systems. In the 1990s, the growth of regional trade agreements combined with the constraints of the MFA encouraged firms in the United States and European Union to create cross-border production arrangements in nearby low-wage sites. These were usually sites with preferential or unrestricted trade access to Western markets. Mexico’s *maquiladora* exports

to the United States, for example, were facilitated by the North American Free Trade Agreement (NAFTA). This arrangement created markets for American-made fabrics and, thereby, protected American textiles jobs. In Europe, “outward processing” similarly links European brands and European-made textiles to clothing manufacturing sites in Turkey, Eastern Europe, and North Africa.

In recent years, commodity chain analysts have focused attention on the opportunities for less developed countries to upgrade their production capacities and move to higher-value-added activities by learning from their buyers. This view has stimulated research into the nature of the relationships among firms, especially the relationships between core buyer firms and their suppliers. In theory, core firms

Figure 3 Leading clothing-exporting countries

Figure 4 The structure of global commodity chains

Source: Adapted from Gereffi, G. (1994). The organization of buyer-driven global commodity chains: How U.S. retailers shape overseas production networks. In G. Gereffi & M. Korzeniewicz (Eds.), *Commodity chains and global capitalism* (p. 98, fig. 5.1). Westport, CT: Greenwood Press.

in the textiles sector are able to choose where and how different tasks are performed. As buyers in a global industry that is overcrowded with sellers, they enjoy a significant bargaining advantage. In practice, however, firms' options are limited. To ensure the timely supply of garments of the required quality, core firms tend to develop close relationships with reliable “preferred” suppliers. In recent years, the capacity of large retail firms to micromanage their suppliers has been enhanced by the standardization of accounting, auditing, and stock control technologies. These technologies have enabled large global retailers (such as Walmart and the Gap) to consolidate their relationships with their key suppliers and increase the range of tasks required of suppliers. These innovations tend to raise entry barriers and lock the less technically sophisticated producers out of global supply networks.

Labor Rights, Gender, and Business Ethics

The International Labor Office (ILO) has estimated that the sector's worldwide workforce was about 30 million workers in 2000. About three quarters (72%) of these workers live in Asian countries. In high-wage nations, textile employment has fallen relentlessly since the 1970s, but it is still a major contributor to manufacturing employment.

The textiles sector has been an important source of employment for women, who often work in onerous circumstances and are consistently paid 20% to 30% less than men. Home-based work and work in small factories or "sweatshops" is commonplace even in high-wage locations. This work is often insecure or "precarious," reflecting the intermittent nature of intermittent production. The sector has therefore featured prominently in studies of gender and development that highlight the hardships faced by women in these industries, as they negotiate the boundaries between waged and unwaged work and between workplaces and households.

The combination of globalized production structures and low wages place the textiles sector at the forefront of global labor rights campaigns. Activists informed by global commodity chain theories have successfully argued that Western buyer firms should be responsible for the labor conditions in their supplier factories. In response, the core buyer firms have introduced corporate social responsibility, corporate philanthropy and employment, and codes of practice that seek to protect their brand's reputation by ensuring that suppliers comply with minimum labor standards. Activists claim that in practice, these voluntary codes are often ignored. However, in countries such as Australia, the codes of practice have been formally incorporated into clothing industry regulation.

Reworking the Labor Process

In the long distant past, whole garments were crafted by skilled dressmakers and tailors. In the factories that emerged after the popularization of sewing machines in the 1880s, production was segmented so that a worker might perform a single task, such as attaching collars

or making buttonholes. Most of this labor was designed as women's work. The vertical disintegration of the labor process increased the efficiency of production but deskilled the clothing workforce and reinforced its gendered division of labor. Nonetheless, the range of styles, sizes, and colors required in clothing markets meant that clothing production was never standardized in the post-World War II Fordist mass production model.

During the 1970s, increasing competition from garments made in low-wage countries forced manufacturers in high-wage contexts to restructure their operations. Firms shifted toward less price-sensitive, niche markets and targeted higher-income consumers' desire for variety, design excellence, and quality. Firms changed their relationships with the market, investing in brand strategies that sought to capture the interest of a loyal clientele. Firms also aimed to offset the advantage of low-wage producers by increasing labor productivity, focusing on quick-turnaround fashion production and on reducing the time and distance between the conception of designs and the delivery of finished goods.

The inherent uncertainty of fashion-oriented markets encouraged manufacturing firms to adopt strategies variously known as "quick response," "just-in-time," or "lean" manufacturing. These involve a set of related innovations, including increasing the number of stock turns per year (equivalently, accelerating the circuit of capital), minimizing inventories, streamlining production to reduce labor costs, and increasing the productivity of individual workers (i.e., work intensification). New technologies of stock control such as Electronic Data Interchange (EDI, which links factories to retailers), computer-aided design, and computer-controlled laser cutting also increased productivity by eliminating many of the low-skilled jobs that once supported the core activity of sewing cloth. Because of this fragmentation, clothing production has come to be seen as exemplifying the numerical and task flexibility associated with post-Fordist production systems.

Reorienting to fashion production encouraged the development of small, specialized firms and altered the relationships among firms in vertically disintegrated supply chains. Modern

“fast-fashion” systems further accelerate the production cycle as their constant design innovations disconnect fashion from seasonal rhythms. Since fast fashion is organized around time imperatives, it encourages localized production “close” to target markets, brings retailers and manufacturers into close alliances, and promotes the integration of fashion-related manufacturing and service activities across multiple sectors.

In the 1980s, the specialized and flexible clothing production sectors of districts such as Emilio-Romagna in Northern Italy became the prototypes for a new paradigm of industrial production based on specialization, flexibility, and agglomeration. In this model of industrial organization, subcontracting strategies favor small, specialized establishments able to quickly adjust their production profiles to changing market trends. This format generates localized networks of highly specialized small firms with complementary expertise. External economies emerge as firms share innovation-promoting “ways-of-doing” knowledge and develop shared infrastructures, which encourages place-based agglomerations. Because firms gravitate to places that are able to supply their labor requirements—both highly skilled design workers and basic sewing machinists—clothing districts are found in the world’s richest cities, especially places with large immigrant communities such as New York and Los Angeles.

Fashion, Agglomeration, and Place

Because clothing and textiles adorn the body, the textiles sector is deeply linked to the worlds of fashion, consumption, and lifestyle. Rapidly changing fashion styles mean that clothing is increasingly regarded as a perishable commodity. In advanced capitalist economies, anticipating and shaping consumers’ fashion preferences is therefore an increasingly important aspect of clothing and textiles businesses. The crucial role of fashion in structuring the global production system exemplifies the increasing importance of symbolic knowledge in regional economic competitiveness. Within places, the cultural embeddedness and the design intensity of fashion promotes links among fashion-oriented industries,

creating agglomerative tendencies that are increasingly associated with “creative city” and “cultural economy” discourses.

Conclusion

The textiles sector is characterized by international commodity flows but also features extensive spatial agglomeration. It appears that these globalizing and localizing forces are operating together in a mutually reinforcing way so that the industry is concentrating at the nodes in the global networks. As regulatory barriers are relaxed, the sector appears to be increasingly characterized by complexes of competing and cooperating agglomerations.

THALES

(CA. 626–CA. 548 BC)

Thales, born in Miletus, was a pre-Socratic Greek philosopher, the first natural philosopher who belonged to the Milesian school along with Anaximander and Anaximenes. Unfortunately, we do not have any of his writings; however, his importance in the field of geographic studies is due particularly to his views about the nature of Earth and his search for rational explanations through the observation of natural phenomena and avoidance of mythological beliefs.

According to Herodotus, Thales predicted the solar eclipse that occurred on May 28, 585 BC, but he is also said to have calculated the length of the seasons, the solstices, and the lunar phases; to have learned from sailors how to orient himself thanks to the stars (especially those belonging to the constellation Ursa Minor); to have conceived of diverting the Halys River (now called the Kizilirmak); and to have studied the yearly floods of the Nile, wrongly believing, however, that they were caused by seasonal winds.

In Egypt, Thales studied geometry and then introduced it to Greece. During his journeys through Egypt, where he visited the Nile delta, Thales observed the areas where water encounters land and elaborated a peculiar cosmological theory based on the idea that water is the origin (*arche*) of all things and that Earth rests on this substance. According to Aristotle, he may have found support for his idea in the fact that humidity can be found almost everywhere in the world and that moisture provides living beings with nourishment.

Regarding his idea of the shape of Earth, there are two schools of thought: Some commentators argue that he imagined a circular, flat, and thin world, whereas others support the theory that he believed that the planet was spherical. The explanation that he gave of a natural phenomenon such

as earthquakes is strictly related to the theory of water as the fundamental principle of the world. In his opinion, in fact, lands fluctuate and shake because of the rough motion of the oceanic sprawl on which they float.

THERMAL IMAGERY

Imagery produced by the sensing of thermal energy emitted or reflected from the objects that are sensed is called thermal imagery. Thermal energy or thermal infrared radiation refers to electromagnetic waves in the 3.5- and 20- μm (micrometer) portion of the spectrum. Most thermal remote sensing applications make use of the 8- to 14- μm range. Earth's surface and atmosphere radiate thermal energy outward owing to heating by solar irradiation and by Earth's internal heat flow. By measuring and recording such emitted radiation in parts of the thermal region of the spectrum, sensors can produce very informative data (as imagery) that provide both distinctive signatures and/or indirect indications of properties of materials, which are sensed, such as vegetation, soil, rock, water, and people. Thermal imagery can be acquired by thermal remote sensing techniques.

Thermal Radiation Principle

Any objects on Earth's surface and in the atmosphere at a temperature above absolute zero in

Thermal-infrared imaging sensors on NASA's *Ikhana* unmanned research aircraft recorded this image of the Grass Valley/Slide Fire near Lake Arrowhead/Running Springs in the San Bernardino Mountains of Southern California just before noon on October 25, 2007. The three-dimensional processed image is a colorized mosaic of images draped over terrain, looking east. Active fire is seen in yellow, while hot and previously burned areas are in shades of dark red and purple. Unburned areas are shown in green hues.

degrees Kelvin can emit thermal radiation due to kinetic energy of molecules within the objects. They are sources of thermal infrared radiation. The thermal radiation obeys Planck's function, which describes the relationship between the object (blackbody) temperature and its spectral radiant exitance. A *blackbody* is an object that is a perfect emitter and absorber. Theoretically, two physical laws can be used to describe the behaviors of thermal radiation: the Stefan-Boltzmann law and Wien's displacement law. The former is related to the Planck's function and is used to calculate the maximum spectral radiant exitance with a known blackbody temperature, and the latter describes the relationship between the true temperature of a blackbody in degrees Kelvin and its peak spectral exitance or dominant wavelength. However, no objects in nature are true

blackbodies, but rather are graybodies such as vegetation, soil, rock, and so on. Therefore, when applying the two physical laws to describe the thermal radiation, an emission efficiency factor called emissivity (ϵ) should be considered. The ϵ is generally a function of wavelength, and it is a factor that describes how efficiently an object radiates energy compared with a blackbody. When $\epsilon = 1$, the object is a true blackbody. So ϵ for all graybodies is less than 1. When sensors record the thermal radiation emitted by objects, thermal infrared atmospheric transmittance has to be considered because of its absorption. Those wavelength regions that allow the major portion of thermal energy to pass through the atmosphere are called atmospheric windows. Currently, there are two major thermal infrared atmospheric windows that can be used for imaging thermal energy: (1) 3 to 5 μm and

(2) 8 to 14 μm ; especially the 8- to 14- μm window is used by most orbital thermal sensors.

Thermal Imagery Acquisition

Thermal imagery can be acquired by two types of remote sensing sensors: (1) across-track thermal scanners and (2) pushbroom linear and area-array charge-coupled device (CCD) detectors.

The thermal scanner became commercially available during the late 1960s. It is an optical-electronic scanning system. Quantum or photo detectors are typically used for this purpose. These detectors are capable of very rapid response. They operate on the principle of direct interaction between photons of radiation incident on them and the energy levels of electrical charge carriers within the detector material. The

earlier models directly recoded thermal energy on the film to form an image. Newer systems record thermal data digitally. Both analog (film) and digital scanners measure and record temperature variation of an object in two dimensions. The modern scanning systems are capable of imaging temperature resolution on the order of 0.1 °C. An across-track thermal scanner image is a pictorial representation of detector response on a line-by-line basis.

So far, most thermal data were collected with a single detector and a scanning mirror as discussed above. It is now possible to make use of both linear and area-array (sometimes referred to as “staring” focal-plane arrays) CCD detectors for acquiring thermal imagery. Detector arrays comprising more than $1,024 \times 1,024$ elements are now available and provide low noise and state-of-the-art sensitivity for extremely low variation of object temperatures. The individual CCD detectors also operate on the same principle as a single detector working for the across-track thermal scanner. But due to the capability of CCD detectors to view the ground resolution element for a longer time, the thermal imagery has improved significantly in terms of both radiometric and geometric resolution.

Thermal Imagery Application

The prominent remote sensing platforms collecting thermal imagery include Landsat Thematic Mapper (TM) band 6 (120-m spatial resolution) and Enhanced TM Plus band 6 (60-m spatial resolution), Terra/Aqua Moderate Resolution Imaging Spectroradiometer (MODIS) bands 31 and 32 (1-km [kilometer] spatial resolution), Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) bands 9 to 14 (90-m spatial resolution), and National Oceanic and Atmospheric Administration (NOAA) Advanced Very High Resolution Radiometer (AVHRR) bands 4 and 5 (1-km spatial resolution). The prominent airborne platforms collecting thermal imagery include the Advanced Thermal and Land Applications Sensor (ATLAS) instrument flown on the NASA (National Aeronautics and Space Administration) Stennis Lear jet (ATLAS thermal bands 10–15) and the Itres, Canada, Thermal Airborne Broadband Imager (TABI). Thermal imagery has

been successfully applied in diverse tasks such as determining the rock type and structure, locating geological faults, mapping soil type and moisture, detecting and mapping the extent of active wildfires, studying evapotranspiration from vegetation, detecting and mapping the extent and characteristics of thermal plumes in lakes and rivers, and determining urban heat islands.

THORNTHWAITE, C. WARREN (1899–1963)

Charles Warren Thornthwaite was one of the most influential climatologists of the 20th century. His work on the water balance concept remains a legacy today in environmental and scientific disciplines. Scientists used his water balance methods to depict regional climates and to solve environmental and geographical problems specifically related to agriculture and water balance. Thornthwaite realized that a more logical approach to the moisture factor in climate was needed. As a result, he developed the concept of potential evapotranspiration (PE)—evaporation and transpiration from a uniformly covered ground surface of vegetation that would be adequately supplied with water. Empirical relationships were developed to determine PE based on

simple measures of air temperature and a latitude factor to adjust for day length and variables either measured at numerous weather stations worldwide or determined from Earth-sun relationships. Thus, PE, expressed as a depth measure, can be directly compared with precipitation to arrive at estimates of surplus and deficits for the soil-vegetative system and in hydrology to determine runoff.

Thornthwaite had a major impact on the field of climatology through his development of a rational classification of world climates based on water balance principles and the concept of PE. His career spanned several positions, from which he crafted ingenious applied analyses and contributions: Chief of the Climatic and Physiographic Division of the Soil Conservation Service in the Department of Agriculture, a consulting climatologist for Seabrook Farms in New Jersey, and an originator of a consulting company, C. W. Thornthwaite Associates. He also established the Laboratory of Climatology in Centerton, New Jersey. Thornthwaite was elected as the first president of the World Meteorological Organization's Commission on Climatology in 1951. He received the prestigious Cullum Medal of the American Geographical Society and the Outstanding Achievement Award from the Association of American Geographers. In *The Task Ahead*, published in 1961, Thornthwaite provided young scholars with a vision of the task ahead in climatology—a vision valid to this day and one that included scientific grounding in energy and water budget theory and analyses. Last was his contribution to urban geography through his dissertation under Carl Sauer. Thornthwaite's approach was a classic one in what was later to become a strong spatial tradition in the discipline.

THREE-DIMENSIONAL DATA MODELS

Three-dimensional (3D) data models focus on portraying the third dimension of physical objects and phenomena through the integration of semantic, geometric, and spatial data relationships. Fundamentally, this is a perspective different from the static, 2D or bird's-eye perspective on the world in traditional spatial data modeling. There are two approaches to modeling the third dimension in geographic information systems (GIS): (1) quasi-3D data modeling and (2) true 3D data modeling.

In the first approach of quasi-3D data modeling, a geographic phenomenon can be constructed as a surface in which a given geographic location is defined by a set of x and y coordinates, and a single value z can be assigned to this location. The value z can be elevation above sea level or any other abstract value associated with the represented phenomenon, for example, population density. In the elevation example, the displayed land surface in a model would be close to what we actually see in the real world (Figure 1). In the population density example, the height of the displayed surface would be the population density at a location at a particular time. This type of approach can efficiently handle 3D visualization through a number of ways, such as generating the surface from value z , draping raster images onto

Figure 1 Three-dimensional display of digital elevation model for the county of Greene, Missouri

Source: Author.

the surface (e.g., aerial photos), visualizing terrain from one point to another, and animation (e.g., the function of creating fly-through video). As this type of approach is insufficient to represent data with multiple z values, it cannot be regarded as true 3D data modeling. In addition, this approach is not capable of representing the space above, beneath, and between surfaces in data structure. It is therefore known as quasi-3D data modeling or 2.5D data modeling. Quasi-3D or 2.5D data models are not suitable for 3D solid objects that are continuously distributed in the 3D space, such as ore bodies. From another point of view, quasi-3D or 2.5D data models are mainly used for visualization purposes and cannot support full-3D data querying and analysis, which require geometric and topological relationships.

Given the limitations of conventional 2D and quasi-3D (or 2.5D) data models, a different approach is needed for true 3D data modeling. In true 3D data models, a geographic phenomenon can be constructed as a 3D object, such as a solid cube. Any point in space is specified by three locational values of an x coordinate, a y coordinate, and a z coordinate (e.g., height or depth)

and one or multiple values related to the phenomenon, for example, different geological layers (Figure 2). It should be noted that in true 3D data models every pair of x and y coordinates with multiple z coordinates allows the presentation and manipulation of full information relevant to 3D solid objects.

For 3D data model design, topology is considered the most important concept. Topology can be specified as a set of rules that model how adjacent or neighboring spatial features connect and link to each other in spatial data models. These spatial features can be points, lines, polygons, surfaces, or bodies (volumes). Past studies have reported several 3D data models. For example, Carlson (1987) developed the simplicial complex, including 0-simplex, 1-simplex, and 3-simplex, to describe point, line, surface, and volume. Moleenaar (1990) proposed a model of 3D Formal Data Structure, which contains nodes, arcs, edges, and faces to denote points, lines, surfaces, and bodies. Pilouk (1996) introduced the Tetrahedral Network (TEN) to model 3D objects with vague boundaries based on the 2D Triangular Irregular Network (TIN). Coors (2003) designed the Urban

Figure 2 Three-dimensional geologic and seismic velocity model of the Santa Clara Valley area

Data Model, using planar convex faces to represent bodies and surfaces. Lee (2007) proposed the 3D Navigable Data Model, which is a network representation of building factoring pedestrian movements based on a 3D Geometric Network Data Model (GNM) that he developed. In the 3D GNM, a set of nodes denote 3D objects in primal space, and a set of edges denote the spatial relationships between 3D entities in primal space. These models adopted different ways to define topological relationships, that is, spatial relationships between spatial objects, such as intersection, connectivity, direction, containment, and adjacency. The clearly defined spatial relationships enable researchers to describe spatial objects

with either heterogeneous or homogeneous properties, using different basic elements in their specific models. Moreover, the clearly defined spatial relationships provide a basis for data manipulation, data analysis, and other functionalities, such as computation-based queries, editing and examining specific objects, geometric calculation of volume, overlay, and buffering.

The potential application areas of 3D data models include environmental monitoring, geological and mining analysis, 3D urban mapping, disaster management, transportation planning, hydrological analysis, and military operations. For instance, a 3D geologic and seismic model may assist researchers in predicting the shaking

levels of possible earthquakes. It is worth noting that visualization is the most common usage of 3D data models for practical applications.

The development of true-3D data models has been relatively slow. To date very few commercial software packages provide an analytical environment for true-3D data, and 3D functionality is absent. Three-dimensional functionality may include creating 3D objects, editing and organizing 3D data, querying 3D data, processing 3D data, and analyzing 3D data, including 3D data overlay, 3D data buffering, and 3D network routing. Research efforts are needed to extend the uses of 3D data models beyond visualization by resolving issues related to functionality. These issues may include the use of scalable information according to the problem needs instead of aggregated information, designing better data structures, spatial indexing and database management system (DBMS) that are suitable for 3D data representation and analysis, incorporating dynamic or real-time spatial-temporal data into 3D models for decision making and planning, and developing automated approaches to 3D model construction for large areas.

THREE MILE ISLAND NUCLEAR ACCIDENT

The accident at the Three Mile Island Unit 2 (TMI-2) nuclear power plant near Middletown, Pennsylvania, on March 28, 1979, was the most serious in a commercial nuclear power plant in the United States, even though it led to no deaths or injuries to plant workers or members of adjacent communities. It had major implications for the nuclear industry because it resulted in major changes in the regulatory requirements involving emergency response planning, reactor operator training, radiation monitoring, human factors engineering, radiation protection, and other areas of nuclear plant operations. It also caused the U.S. Nuclear Regulatory Commission (NRC) to tighten and heighten its regulatory oversight.

The accident at TMI-2 was initiated at 4 a.m. by a minor malfunction, or “transient,” in the nonnuclear part of the reactor. The main feed-water pumps stopped running, which prevented the steam generators from removing heat. This event evolved into a series of automated responses in the reactor’s coolant system, and during this time, the relief valve on top of a piece of equipment called “the pressurizer” became stuck in an open position. Misreading of the plant conditions by the operators over a 2¼-hour period before the relief valve was closed and the turning off of an automatic emergency cooling system caused

The Three Mile Island nuclear power plant near Middletown, Pennsylvania, which was the site of a March 28, 1979, power plant accident.

Source: iStockphoto.

the reactor core to become partially uncovered and severely damaged. The major consequences of the accident unfolded over the next week, and it took 1 month to bring the reactor to a cold shutdown.

During the first several days of the accident, communications between the NRC and the site were problematic, which made it extremely difficult for the NRC to obtain up-to-date information from the plant and the utility. The suggestion by the NRC of a possible large-scale evacuation out to 20 mi. (miles) was quite different from the 5-mi. planning requirements imposed by the NRC and Pennsylvania before the accident.

On March 30, midmorning, Pennsylvania Governor Richard Thornburgh's press secretary told reporters that there was no need for evacuation and that people in a 10-mi. vicinity of the plant could remain inside for a while. The only official warning to the public to evacuate came at

approximately 12:30 p.m., when the governor advised pregnant women and preschool children to leave the area within a 5-mi. radius of TMI until further notice. He also ordered schools to close. The advisory to pregnant women and preschool children was lifted on April 9. The governor's warning was the only official warning issued by the government. People in the vicinity of the plant were bombarded by media coverage, which suggested that a major evacuation was imminent. As a result, many people decided to evacuate despite the limited recommendation made by the governor. Approximately 144,000 people within a 15-mi. radius evacuated.

THRIFT, NIGEL (1949–)

Nigel Thrift has long been recognized as one of geography's most imaginative, articulate, and productive scholars. In an exceptionally lengthy series of papers and books, Thrift has made major contributions to the history of geographical thought; introduced a variety of new perspectives ranging from structuration theory to poststructuralist concerns for identity and performativity; advocated a renewed role for regions in geographical analysis; explicated the contingent, contradictory nature of globalization and its implications for regional development; and consistently argued for the centrality of human consciousness, however bounded, in the construction and reproduction of social and spatial relations.

Born in 1949, Thrift earned his PhD from the University of Bristol in 1979. He was stationed briefly in Leeds (1976–1977), spent 4 yrs. (years) (1979–1983) as a research fellow at the Australian National University, and served 3 yrs. (1984–1987) as a lecturer and reader at Saint David's University College, Lampeter, Wales. In 1987, he returned to Bristol, where for more than two decades he was a professor in the School of Geographical Sciences. Between 2003 and 2006, he served as pro-vice chancellor for research at Oxford University. In 2006, he joined the University of Warwick in Coventry as vice chancellor.

Thrift's career both reflected and spurred the enormous intellectual changes in human geography in the late 20th and early 21st centuries. Between 1975 and 2009, he authored or coauthored 110 refereed journal articles and 100 book chapters and wrote, edited, or coedited 39 books. His career began conventionally as an economic geographer with analyses of industrial linkages and markets and multinational corporations,

originally focusing on the specific instance of Australia. This thread has continued in an ongoing form through a sustained interest in organizational theory, which maintained that the specifics of individual corporations were fundamental to the understanding of how markets behaved and changed. Throughout his works runs a nonstructuralist Marxist concern for class, a position that he later extended to a variety of non-class-based forms of social determination. Thrift's worldview takes seriously the complex conditions under which human beings take the world for granted and give meaning to it.

Thrift exhibited a sustained interest in questions of time. No longer could geographers be content with the static geometries of chorology and positivism; social theory had become self-consciously dynamic, portraying every place as a time and integrating into spatial analysis an understanding of how time was socially constructed and, thus, experienced differently under varying historical and spatial circumstances. This work exhibited strong linkages to time-geography, which concerned itself with the movements of individual bodies through the rhythms of everyday life. Thrift also studied the restructuring of time consciousness in contexts ranging from the medieval to the contemporary, including in particular the imperatives of commodity production and capital accumulation. Thrift also played a key role in introducing Giddens's concept of structuration into geography. His paper, "On the Determination of Social Action in Space and Time," published in 1983, was a landmark that both situated structuration theory within the broader intellectual context of "micro-macro" divisions in the social sciences and pointed toward the emerging reconstruction of regional geography.

In the 1990s, Thrift played an influential role in moving geography to new frontiers of poststructuralism, including a variety of concerns with subjectivity, language, representation, discourse, and identity. Although he has never referred to himself as a postmodernist, his theoretical orientations include similar qualities, such as a distrust of broad metatheories, an appreciation for local uniqueness, and an emphasis on social structures and change as inherently open-ended and contingent.

Throughout his career, Thrift has been fascinated by cities as dense nuclei of economic and social transactions, the changing possibilities for economic development afforded by globalization, and the mutations in urban form and life that such transformations entailed. Cities, particularly in the knowledge-driven economies of “soft capitalism,” both reflect and constitute the changing dynamics of social life as contingent constellations of meaning.

If there is any theme that permeates Thrift’s multitudinous works, perhaps it is his sustained interest in connectivity of one sort or another. His papers addressed the relations among bodies and individuals, the diffusion of information, the reciprocal relations between knowledge and power, and the increasingly globalized exchanges of human, symbolic, and financial capital. Thus, he exhibits a consistent concern for the flows of information and knowledge that shape individuals’ conceptions of themselves and one another and that play a major role in the routinized reproduction of social relations. Such linkages reflect and constitute the changing face of capitalism at a variety of spatial scales, ranging from the most intimate and local (e.g., the body) to the international and global.

Thrift’s concern with the differential regional effects of globalization was materialized in a variety of case studies. He has worked extensively on the restructuring of the British space-economy in the face of globalization and mounting social and regional polarization, including the rise of the Greater London region and the nature and impacts of various services such as accounting, property and real estate, and surveying. He also examined other European regions in various contexts, including the rising role of dense human networks in leading innovative regions characteristic of advanced post-Fordist production systems. Thrift also worked extensively on Pacific Asia, particularly Vietnam. These empirical analyses complemented his insistence that regions mattered not only ontologically, that is, as units of empirical analysis, but also epistemologically—that is, no social process was manifested in the same way in different places.

The latter line of thought appealed to geographers who insisted that local uniqueness mattered, many of whom sought to recover regions

from the dustbin of traditional chorology. Throughout the 1980s, the “new regional geography” developed growing linkages to top-down global political economy and to “bottom-up” concerns for living actors and everyday life. Thrift played a key role in articulating this vision of geography, defending it against both positivist and Marxist critics, for whom regional analysis could, by definition, amount to little more than reconstituted empiricism. Unlike chorology, however, the reconstituted regionalism was both theoretically informed and paid great attention to the connections among regions, their linkages to the global division of labor, and the sticky issue of the production of spatial scale. The new regionalism made local uniqueness a valid object of scholarly scrutiny, demonstrating that the local *mattered* in ways that broad models could never discover and that no social process played out exactly in the same way in different time-space contexts. The recovery of regions for social theory obligated the discipline to delve into the intricate dynamics of the local actors who populated them and “made them work”: Thus, the localities school and structuration theory’s focus on everyday life were mutually complementary. This concern with the local extended to his work on the most abstract and globalized of economic sectors, finance.

With Andrew Leyshon, Thrift generated a series of works concerning the international financial system, British financial capital, and banking networks in London. These papers both elucidated the impacts of electronic money and national deregulation and simultaneously demystified money by stressing the key roles played by interpersonal relations predicated on trust and face-to-face contact, including the critical but often overlooked roles played by local milieu, trust, and “institutional thickness,” that is, the cultural context in which financial transactions are always and everywhere embedded. Money, even in its most rarified electronic form, is thus much more than an abstract economic relation, for its real power lies in its symbolic value and links to national and global distributions of social power. Like all social relations, financial systems are inevitably discursively constituted through particular social-cultural practices in different times and places. Such an approach brought a badly needed human quality to a topic dominated

by ethereal understandings devoid of actors and is vital if the new forms of “soft” managerial capitalism are to be understood in all their complexity. Thrift’s writings reveal an understanding that the contemporary forms of capitalism, dominated as they are by finance and information, simultaneously reflect the historic tendency toward increasing commodification of all activities as well as the emergence of a historically unprecedented form of production and consumption, a perspective that eludes the naive optimism and technological determinism of postindustrial theory. The “symbolic economy” calls for new forms of performativity for actors for it to function successfully.

Thrift has exhibited broader concerns for the implications on individual subjectivity of information technology and electronic communications, which are representative of the post-Fordist, digitized “soft capitalism” and its attendant digitized, virtual dimensions. The massive time-space compression unleashed by digital globalization has thus altered the field of possibilities for both nation-states and individual actors in everyday life: The renewed regionalism and reconstituted rhythms of daily life are two sides of one coin. At the level of the corporation and everyday life, Thrift has also taken an interest in the possibilities extended by the widespread use of computational technology and mobile telecommunications. In sum, the contingent, simultaneously determinant interactions between culture and technology form a recurrent theme that runs through his writing.

Thrift has long insisted that geographies are produced by people in prediscursive, practical ways, and he has been one of the discipline’s foremost advocates of theoretical stances that emphasize the contingency of human action. This position stands as a hallmark of the contemporary “cultural turn” in the social sciences, which has led numerous researchers to embed economies in social relations, blurring the artificial distinctions between the “economic,” the “cultural,” the “social,” and the “political.” More broadly, the profound role played by systems of signification, including discourses, language, texts, and representations of all kinds, has led him to forge a nonrepresentational theory of action that stresses performative embodied knowledges; more

recently, he became a leading advocate of nonrepresentational theory. Yet this relational materialist perspective maintains that the global “space of flows” does not float in a disembodied space: Rather, global flows and connections are constructed by human beings who are always embedded in networks of power and knowledge that are themselves part of an ever-changing structural context. Invoking actor-network theory, Thrift effectively abandons the distinction between agents and structures. This view focuses on the exercise of power by actors rather than just the embeddedness of power in networks. Throughout his career, Thrift has worked assiduously to portray geographies as embodied, embedded, contingent, and ever changing, harnessing the fluidity of spatial relations to demonstrate how they are imbricated in changing human relations of power.

THUNDERSTORMS

Thunderstorms are convection storms comprising cumulonimbus clouds that are accompanied by lightning and thunder and moderate to heavy precipitation. Additional attributes may include strong winds, hail, and/or tornadoes. In terms of the hierarchy of atmospheric scales of motion, thunderstorms are classified as *mesoscale* systems, the second smallest after microscale systems. Mesoscale systems have a typical life span of 1 hr. (hour) or more and range in size from a few kilometers to 100 km (kilometers) in diameter. Based on system duration, structure, and formation, thunderstorms are classified as ordinary cell, multicell, or supercell and may or may not be considered severe.

Also known as air mass thunderstorms, ordinary cell thunderstorms have the simplest structure and formation conditions of the three major thunderstorm categories. These storms materialize within warm, humid, and unstable air mass environments amid often weak vertical wind shear

(i.e., wind speed and direction do not change greatly with height). Ordinary cell thunderstorms are usually compact (<1 km in width), nonsevere, and not associated with mechanical lifting mechanisms (e.g., frontal uplift). Ordinary cell thunderstorms typically undergo a three-stage sequence of development: cumulus, mature, and dissipating. The cumulus stage is characterized by rising air parcels or thermals that result from differential surface heating. Updrafts dominate this growth stage, and lightning and thunder are absent. As the cloud particles enlarge and become heavier, the updrafts may not be sufficiently strong enough to sustain their suspension, and the cloud particles begin to fall as precipitation. The manifestation of a precipitation downdraft ushers in the mature stage, the most intense phase typified by strong updrafts and downdrafts, heavy precipitation, lightning and thunder, and gusty surface winds. The air mass thunderstorm begins to dissipate as the warm, humid air source inflow supplying the thunderstorm's energy is suppressed by the precipitation downdraft. The final stage is marked by light precipitation, weak downdrafts, and cloud evaporation. Since the entire development cycle may be completed in less than 1 hr., these scattered storms may be referred to as “popup showers,” for their ability to mature and disperse quickly. Of the approximately 50,000 thunderstorms that occur each day across the world, most are of this ordinary cell variety.

Multicell thunderstorms contain several ordinary thunderstorm cells under various development stages, appearing as a continuous, long-lasting storm. A single thunderstorm cell may initiate new cell development or “daughter cells” along the precipitation outflow boundaries (known as gust fronts) and form a larger cluster of thunderstorms. If the thunderstorms align linearly, this configuration is known as a squall line. Not all squall lines, however, are formed along gust fronts. Frontal and prefrontal squall lines are longer lasting than their ordinary squall line counterparts and are frequently associated with severe weather. Fast-moving squall lines may also produce especially enduring and widespread wind storms called *derechos*, which can produce wind speeds in excess of 100 mph (miles per hour).

Instead of a linear configuration, multicells may also cluster and expand over an extensive

Approaching thunderstorm with lead gust front. Rain-cooled air from the storm moves out ahead of the storm. It ploughs under the warm moist air, forming a flat “shelf cloud.”

Source: National Oceanic and Atmospheric Administration (NOAA) Photo Library, NOAA Central Library; NOAA Office of Oceanic and Atmospheric Research/Environmental Research Laboratories/National Severe Storms Laboratory (NSSL).

region and intensify. Mesoscale Convective Complexes (MCCs) are long-lasting (>12 hrs. or more), nocturnal multicell storm systems that develop in high-moisture environments with weak vertical wind shear, a situation common during the midlatitude summer on the tropics. These slow-moving storms are thousands of times larger than ordinary cell thunderstorms and can produce copious amounts of precipitation. In the maritime tropics, a concentrated thunderstorm cluster around a rotation center may signify the potential for hurricane development.

Supercells are the most intense, most destructive, and rarest thunderstorm type. These storms appear as large isolated cells often ahead of an approaching squall line and can produce large hail, heavy precipitation, and/or tornadoes. In contrast to multicell thunderstorms, supercells are differentiated by a deep, continuously rotating updraft or

mesocyclone tilted away from the primary precipitation downdraft region. This tilted updraft structure enables the continued inflow of moist, humid air into the storm even after precipitation commences, thereby sustaining the latent heat energy supply and enabling the storm to continue for several hours. Supercells may be categorized into three main types, classic, low precipitation, or high precipitation, depending on the updraft and downdraft configuration. Environments with strong contrasts in temperature, moisture, and vertical wind shear support supercell development. These ambient conditions are most commonly found in the North American Great Plains region in spring and early summer; however, supercells are also known to occur occasionally in other midlatitude locations across the world.

The global distribution of thunderstorms is linked to the proximity of maritime tropical air

mass source regions that support prolonged uplift and warmth, conditions largely found in the tropics. In particular, locations in the vicinity of the Intertropical Convergence Zone (ITCZ) are areas repeatedly favored for deep convection. Resulting from the surface convergence of the northeast and southeast trade winds, the ITCZ initiates widespread thunderstorm development in the equatorial region and also in the extratropics depending on its movement relative to the changes in solar intensity. The seasonal migration of the ITCZ creates distinct wet and dry periods in the tropics, but commonly more than 200 days per year are associated with thunderstorm occurrence in regions around Central Africa, Northern South America, and Indonesia/Northern Australia. In East Asia, the ITCZ migration is linked to the monsoonal circulation, referring to a seasonal reversal in wind direction that during summer promotes the inland movement of unstable, warm humid air into the continent.

Thunderstorm activity is also prominent in the midlatitudes, especially in locations that promote air mass interaction. In the conterminous United States, the highest average annual frequency of thunderstorm days (>100 days) occurs in the central Floridian peninsula primarily due to regional sea breeze convergence during the late spring and summer months; a secondary maximum along the Eastern Colorado Rockies occurs as a consequence of summertime convection and leeside cyclogenesis. Although not common, thunderstorms do appear occasionally in high-latitude locations (e.g., Northern Canada) during the warm season if sufficient moisture and an uplifting mechanism are present.

THÜNEN MODEL

One of the first and most influential conceptions of relative location was proposed by Johann von Thünen (1780–1850), a German estate owner interested in economic theory and local agricultural conditions. From his experiences as an estate manager, he observed that identical plots of land would be used for different purposes depending on their accessibility to the market. His book *The Isolated State*, published in 1826, proposed one of the very first models in economic geography. von Thünen's aim was to uncover the laws that govern the interactions of agricultural prices, transport costs, and land uses as landlords sought to maximize their profits.

The concept of economic rent, also called location rent, a relative measure of the advantage of one parcel of land over another, is central to von Thünen's model of agricultural land use. Differential rents may result from variances in productivity of different parcels of land and/or variances in the distance from the market. von Thünen demonstrated that rent is the price of accessibility to the market. In other words, rents decline with the distance from a market center because transport costs rise accordingly.

To explain agricultural land use, von Thünen described an idealized agricultural region about which he made certain assumptions. He envisioned an isolated state with a large city serving as the only market. A uniform plain surrounded the city. There were no extraneous disturbances in this idealized landscape; social classes and government intervention were absent. The cost of transport to the central town increased at a rate proportional to the distance. He concluded that near the town will be grown those products that are heavy or bulky in relation to their value and that are consequently so expensive to transport

Figure 1 The von Thünen model's bid-rent lines and associated land uses. Given that transport costs erode profits with distance from the market, the Thünen model describes a simplified agricultural system in which land uses change according to prices and transport costs.

Source: Adapted from Wikimedia Commons.

that the remoter districts are unable to supply them. With increasing distance from the town, the land will progressively be given over to products that are cheap to transport in relation to their value. Farmers near the central market pay lower transport costs than farmers at the margin of production. Farmers recognize this condition, and they know that it is in their best interest to bid up the amount that they will pay for agricultural land closer to the market. Bidding continues until bid rent equals location rent. At that price, farmers recover production and transport costs, and landowners receive location rents as payments for their land. Competitive bidding for desirable locations cancels income differentials attributable to accessibility. The bid rent, or the trade-off of rent levels with transport costs, declines just far enough from the market to cover the additional transport costs; hence, farmers are indifferent to their distance from the market.

Location rent for any crop can be calculated by using the following formula:

$$R_k = e(p - a) - efk,$$

where

- R = location rent per unit of land at distance k ,
- e = output per unit of land,
- k = distance to the market,
- p = market price per unit of output,
- a = production cost per unit of product (including labor), and
- f = transport rate per unit of distance per unit of output.

When the rent gradient is rotated around the market town, it becomes a rent cone, the base of which indicates the extensive margin of cultivation for a single crop grown at a single intensity.

Concentric rings or belts will form around the town, each with its own particular staple product. From ring to ring, the staple product will change.

von Thünen was acutely aware that many conflicting factors—physical, technical, cultural, historical, and political—would modify the concentric patterns of agricultural land use. He modified some of his initial assumptions—equal transportation costs in all directions, for example—to approximate actual conditions more closely. Although he retracted the condition of a single-market town, he did not elaborate on the effects of several competing markets and a system of radiating highways. We can presume, however, that the tributary areas of competing markets would have a variety of crop zones enveloped by those of the principal market town and that a radiating highway system would have produced a “starfish” pattern.

TIMBER PLANTATIONS

There are approximately 140 million ha (hectares) of tree plantations worldwide, of which 78% are classified as “productive” and are used primarily for wood and fiber production, while

22% are “protective” and are established primarily for soil and water conservation. The extent of both types of plantations has grown over the past two decades, with productive plantations increasing by approximately 2.2 million ha/yr. (per year) and protective plantations increasing by 380,000 ha/yr. between 1990 and 2005. In both types of plantations, pines are the most commonly planted species. Where tree plantations have been established, they have created both benefits and negative consequences, with the balance varying from one location to another.

Benefits

While tree plantations constitute only 3.5% of the world’s forested area, they are approaching 50% of global wood production. In addition to timber production, tree plantations are an important source of fuelwood in many parts of the world and can provide income from the sale of nontimber forest products (NTFPs) harvested from plantations. While NTFPs account for a much smaller portion of the revenue from plantations than timber, they can be locally important. For example, in the Ecuadorian Andes, an edible mushroom that grows in association with planted pines is harvested and provides an additional source of income. In recent decades, tree plantations have also been valued for their ability to sequester carbon in tree biomass, thereby playing a role in decreasing atmospheric carbon dioxide concentrations. In some cases, tree plantations can also sequester carbon in the soils where they grow. However, this depends largely on the land use prior to plantation: When plantations are established on croplands, soil carbon generally increases, while conversion of pastures or native forests to plantations generally causes a loss of soil carbon.

Costs

Although tree plantations can provide many benefits, there is increasing evidence that they can also cause the deterioration of ecosystem services, in particular water provision. Plantation establishment can decrease stream flow and groundwater recharge, cause acidification of stream

A slash pine plantation in Georgia, United States. Although slash pine has the most limited range of the major Southern pines, more of it has been planted than any other Southern pine, or for that matter any timber species in North America.

Source: Jeff Vanuga, USDA Natural Resources Conservation Service.

water and soils, and produce soil salinization. In many parts of the world, timber plantations have caused additional problems where the exotic species used have become invasive. The invasive spread of commercial plantation species has been recognized as a major threat to native biodiversity in South Africa, New Zealand, Australia, South America, and Hawaii.

Conclusion

The balance between the benefits and costs of tree plantations depends largely on the location in which they are planted. In particular, the type of soils, hydrology, and prior land use, as well as the

condition of the landscape prior to plantation establishment, play an important role, as do the kinds of species used and the way in which the plantations are managed. The degree to which tree plantations can be considered a land use that contributes to environmental sustainability depends on how they influence the provision of ecosystem goods and services, including not only timber and fuelwood but also carbon, water, and biodiversity.

TIME, GEOGRAPHIES OF

The fast pace of modern life and the complex uncertainties of environmental change have led both human and physical geographers to question their understanding of time. Since the 1960s, there has been a significant shift away from chronological, linear conceptions of time toward understandings that examine it as nonlinear and chaotic, something experienced as dynamic and interconnected with different spaces and places. An increasing range of conceptions and debates is emerging under the heading “geographies of time.” Of particular interest from a human geography perspective are ideas concerning social time, such as geographies of rhythms and lived time, which explore people’s everyday experiences of time. Critically, scholars are increasingly debating whether time should still be conceived independently from space, a dualism prominent throughout geography.

Social Time: The Geographies of Rhythms

Social time essentially focuses on social content, recognizing that the way in which people experience time is dictated by a range of social processes. Jon May and Nigel Thrift provide a comprehensive discussion of social time, identifying four domains that interact to produce people’s experience or sense of time. These domains invoke a way of interpreting experiences through considering the rhythms they generate. Rhythm is used in its widest sense to identify anything from

a repetitive process to a recurrent pattern. Anne Buttimer provides an in-depth discussion of time-space rhythms, emphasizing the complex interactions of people’s sensations and representations of time and space.

The first domain considers the variety of cycles and timetables people are subject to, some of which are fixed, such as tidal movements, while others are relatively applied, for example, a woman’s menstrual cycle. Most, however, are constantly under negotiation; take, for instance, the socially constructed pressure of shift work, which requires people to adjust their circadian rhythms to fit in with factory hours or differing time zones in order to meet the demands of the job.

The second domain relates to the regulation or demarcation of time for specific activities. For example, in many Western societies, the prescribed Monday to Friday working week is closely monitored by time sheets and surveillance mechanisms, while the weekend is often equated with family or leisure time. When either time interferes with the other, for instance, taking work home, these norms are broken, disrupting the regulation of social time and demonstrating the combination of forced and voluntary rhythms that make up daily life.

The third domain involves the increasing array of tools and technologies designed to expressly monitor, inform, or direct how people allocate time. Many of these have been around for millennia, from the calendar to various forms of the clock, both of which reinforce the sensation of time moving forward in a linear fashion. The advent of mass transportation and communications led to what is termed the standardization of time, as clock time became uniform the world over. These technologies are often described as leading to time-space compression, perpetuating the perception of an increased pace of life. They often dictate rhythms of particular representations associated with saving time, or being more productive with the time available.

The final domain relates to the influence of particular texts in demarcating what should be done at particular times of the day, year, and so on. From the Julian calendar of AD 1020, which dictated everything from when to pray to when to plough, to Benjamin Spock’s *Common Sense Book of Baby and Child Care* (1946), which

told mothers when to feed and put their children to bed, there has been a proliferation of texts advising people of a particular geography of rhythms around the appropriate time to perform different tasks.

Lived Time

Modern information and communication technologies are proliferating people's capabilities within the moment through instant real-time interactions. Geography is now turning its attention to understanding this and conceptualizing the present or lived time. Many commentators identify the way time has been turned into a product that can be bought and sold, often called the commodification of time. There is a debate around both how to express the present and to what degree it is influenced by past experiences and future intentions. Attention is turning to how individuals perform or what they choose to do in any particular moment, given a world that is transitory and full of multiple possibilities of action.

Time-Space

Human geographers are increasingly arguing that time and space need to be conceptualized interdependently, raising the question of whether there should be an entry dedicated purely to the geographies of time. Doreen Massey argues that this interdependence does not signal the removal of the differences between the two dimensions and that they still require defining but not in the dualistic sense of space not being time and vice versa. Social time, geographies of rhythms, and lived time are all implicitly spatial, as how time is experienced depends on the spaces and places in which the experience is lived. In today's world, there is a much more complex restructuring occurring than simply the acceleration of life and collapse of space, and geography's constantly evolving dialogue on time and space puts it in a strong position to begin critically analyzing this process.

TIME-GEOGRAPHY

Time-geography refers to a set of concepts and a way of thinking that offer a notational system to describe and analyze individuals' and populations' existence, coexistence, constraints, and conflicts in time-space. The time-geographic approach was originally presented in the late 1960s by Torsten Hägerstrand, a well-known professor of human geography at Lund University, Sweden. Time-geography captures complex processes of change on different scales in time and space and is therefore useful for analyzing various topics and problems.

The time-geographic lines of thought are directly linked to Hägerstrand's experiences as the son of an elementary schoolteacher who sought to impart "knowledge about their home district." Hägerstrand found the prevailing academic thinking, which grouped phenomena according to their degree of similarity, to be deficient; his alternative approach was to group phenomena according to their proximity in time and space.

The theoretical roots of time-geography are found in Hägerstrand's thorough empirical fieldwork in Asby parish in Southern Sweden. He and his wife spent several summers biking there searching for houses (or their remains) abandoned by emigrants to the United States during the 19th century. Then, the dominant understanding

among researchers was that each empty house had been the home of an emigrant family. The Asby fieldwork made Hägerstrand question this view, since the resource base surrounding the empty houses was too poor for subsistence—much less for buying a ticket to America. By studying the population in the Asby parish books, individual by individual, he concluded that the emigrant families were those that were relatively well-off but still too poor to find in Asby a place better than their American dream. They sold their houses, and a chain of movements started, with poorer families moving from low-income houses to better ones. As a result, farms that operated under the subsistence level were left empty. Following the individual inhabitants of the houses was the only way to find out who left which house for a better life in America. Houses and people come in many different kinds, but they must be considered together to reevaluate the dominating theory.

In time-geography, the two dimensions of time and space (place, region) are united into a time-space in which processes involving different phenomena can be discerned, irrespective of whether such phenomena are living or nonliving. Each individual is born or created at some point in time, exists during a time period, and dies. This process describes a time-space biography of an individual human being, but since time-geography also includes nonliving phenomena, the more general concept of individual path (trajectory) is introduced. Individuals of the same bounded region (time-space) constitute a population. A bounded region can be defined at different scales: the globe as a whole, a continent, a country, or any locality on the globe. In each region in time-space, individuals (from one or more populations) get in touch with other individuals, and when they move (or are moved), they decouple from one bundle of individuals with whom they were in touch and couple with another bundle. Time-geography facilitates analysis of opportunities for individuals to get in touch with one another and of the constraints on and consequences of such coupling, and it provides tools for dynamic life cycle analysis. For example, environmental problems may be described by the extraction (decoupling) of raw materials in a region and their transportation to a place where they are manufactured (put into new

combinations). Manufacturing is performed at a place by labor, using tools and machines according to procedures that steer the work process, constituting a pocket of local order. Then the product is decoupled from the manufacturing location, transported, and sold. Through the sale, the output is coupled with the customer, who uses the product for reaching the goals of his or her projects. Eventually, the output is worn out, decoupled from the customer, and put in touch with other worn-out individual products at a waste collection center or maybe recycled.

Human individuals performing activities in their projects meet three types of constraints: (1) *coupling constraints* (they must be able to get in touch with another individual at a specific location in time-space in order to fulfill their obligations; e.g., parents have to get their children from day care in the afternoon); (2) *capability constraints* (knowledge, skills, and tools available); and (3) *authority constraints* (regulations, laws, and power relations in social bundles). All these shape the individual's trajectory through time and space in the rhythms of everyday life. Opportunities for individuals to get in touch with one another are revealed by their time-space prisms. Individuals whose time-space constraints prohibit their prisms from intersecting are never afforded the opportunity to meet in person. Geographers such as Alan Pred used this model to describe regional systems of social and economic activity, in which the composite trajectories of individuals reproduce larger social structures in time and space. Time-geography thus became a means of representing and analyzing how social relations were manifested through everyday life in all its temporal and spatial boundedness. Critics of time-geography often argued that it lacked a sufficient account of power and social relations, as well as an adequate theory of human subjectivity.

The time-geographic approach is sometimes taken to be synonymous with its notational system. The notational system is a way of describing the concepts of time-geography, and it is the outcome of Hägerstrand's struggle with the shortcomings of common language to explain his thinking. The notational system is simple and powerful. It can be applied to show how individuals from different populations are born/produced, couple, decouple, move, stay at a

Figure 1 Some time-geographic concepts exemplified by the notational system.

Source: Author.

place, and die/are destroyed—in short, the elementary occurrences in an individual's life.

Time-geography is used for researching environmental problems, energy use, virtual and physical mobility/communication, migration studies, time-use studies, and people's rhythms in daily life. Hägerstrand's time-geography includes the basic principles behind the development of

geographic information systems and was influential in the formulation of structuration theory.

TIME-SPACE COMPRESSION

If geography is largely concerned with how human beings are differentially located over the Earth's surface, a vital part of that process is how we know and feel about space and time. Although space and time appear as “natural” and outside of society, they are in fact social constructions; every society develops different ways of dealing with and perceiving them. Time and space are thus socially created, plastic, mutable institutions that profoundly shape individual perceptions and social relations. The sociologist Anthony Giddens uses the term *distanciation* to describe how societies are stretched over time and space and how this process itself varies temporally and geographically. Because the economy cannot be detached from other realms of social life, time-space compression is more than simply an economic phenomenon. By changing the time-space

prisms of daily life—how people use their time and space, the constraints they face, the meanings they attach to them—time-space compression is simultaneously cultural, social, political, and psychological in nature. This issue elevates the analytical significance of relative space, in which distances are measured through the changing metrics of time and cost, above that of absolute space, the traditional Cartesian form that characterized most Enlightenment forms of geography, which portrayed distance in fixed, unchanging terms devoid of social roots.

The Concept of Time-Space Compression

Time-space compression involves the myriad ways in which human beings have attempted to conquer space, to cross distances more rapidly, and to exchange goods and information more efficiently. The analysis of time-space compression places emphasis on the connections and interactions among places (and the people who live within them, for connections are always embodied) rather than on individual places per se. For example, in the simplest sense, using the maximum transportation speed at various historical moments as a measure, the world became 60 times smaller between 1500 and 1970, when we compare the speed of airplanes (say, 600 mph [miles per hour]) with that of medieval sailing vessels (10 mph) (Figure 1). By increasing the velocities of people, goods, and information, the world is made to feel smaller even as interactions are stretched over larger physical distances. The term *compression* is therefore misleading: Every round of time-space compression involves an expansion in the geographic scale of social activities. This idea is often taken to mean that space ceases to have relevance. Despite the fashionable use of unfortunate expressions such as the “death of distance” or the “annihilation of space,” the fact remains that geography is a stubbornly persistent feature of human life. Rather than the “annihilation of space,” it is healthier to talk of how one space-time regime displaces another. Far from shrinking the world evenly, successive revolutions in the structure of time and space have left it misshapen, as some places were brought together relationally more than others. Moreover, reducing time-space compression to simple reductions in transport times fails to do justice to its deeply phenomenological dimensions and the complexity with which these two dimensions

Figure 1 Time-space compression reflects and generates a shrinking world. Historically, rising velocities of transportation have reduced relative distances across the globe.

Source: Author.

are wrapped up in social life and their political and ideological origins and associations.

Time-space compression occurs at multiple spatial and temporal scales, all of which interact with one another, including long-distance networks of trade that historically sutured cities, empires, and, later, nation-states together into interactive wholes; political formations in which the state integrated diverse peoples and places under a single authority, often through tribute, taxes, or conscription; and the ideological and psychological dimensions of how ideologies perceive and represent Others, the

discursive and symbolic representations of foreign or distant places that define community, identity, and the here and now. This process, of course, depends heavily on the relative and differential abilities of social formations to link places together or, in an older nomenclature, to conquer the “friction of distance.” Whenever the consequences of actions in one area spill over into others, time-space compression is at work. Whenever new networks of trade or migration appear, tying together places through flows of commodities and innovation, time-space compression can be detected; whenever a new

medium, communication technology, or widespread ideology, whether it be the book or a religion or the Web, brings together subjects into epistemic communities bound together over vast distances, time-space compression is in the making; whenever the spatial scale of social relations expands, such as from the city to the nation-state or from states to empires, time-space compression is evident; whenever new technologies expand the conceptual horizons of people or social institutions bind them together in a novel manner (such as “citizenship”), time-space compression occurs; whenever the division of labor collapses people into dense wads of humanity, such as the city or the factory, time-space compression can be detected. One way to approach time-space compression is by looking at how external shocks to a society—diseases, invasions, technological innovations, wars—reverberate through local social relations of class, gender, and ethnicity to change inhabitants’ views of time and space and their fabric of daily life. Conversely, locally generated changes may scale-jump to become regional, national, or global in scope. Time-space compression can be studied by examining the changes in daily life that ensued as new technologies, cultures, and forms of social cohesion were introduced and older ones concomitantly annihilated.

The Evolution of Time-Space Compression

Time-space compression is as old as human civilization itself. Early changes in transportation technology, such as the wheel and keel, were instrumental in the development of centralized empires. Many cultures (e.g., the Romans) developed road or canal networks to shuttle people and goods between places. The Mongols and the Incas created messenger systems using horse riders and runners, respectively. The Renaissance and the Enlightenment exemplified the intellectual changes of early modern time-space compression, including the Copernican revolution and perspectival painting. Printing greatly enhanced the distancing of social intercourse, allowing widespread contacts and diffusion of ideas without face-to-face contact. These changes were important moments in the scalar jump from the city-state to the nation-state, the most important social and political unit of the modern era, homogenizing local cultures and economies by

incorporating them within even larger units of social and political control.

The rise of capitalism, and the Industrial Revolution in particular, generated enormous improvements in transportation and communications that significantly reduced travel times between places. For example, the travel time between Edinburgh and London, a distance of 640 kilometers, was roughly 2,000 min. (minutes) by stagecoach in 1658. By the 1850s, with the arrival of the steam locomotive, travel time had been reduced by two thirds, to 800 min. In 1988, the rail journey between Edinburgh and London took 275 min. When the line was electrified in 1995, travel time was reduced to less than 180 min. By airplane, it takes less than 60 min. today. Thus, while the absolute distance between the two places remained the same, the relative distance was reduced by 1,940 min. over 350 yrs. (years), or roughly 5 min./yr.

Air transportation provides spectacular examples of time-space convergence. In the 1930s, it took a plane between 15 and 17 hrs. (hours) to fly over the United States from coast to coast; modern jets now cross the continent in about 5 hrs. In 1934, planes took 12 days to fly between London and Brisbane, Australia; today the Boeing 747 is capable of flying any commercially practicable route nonstop. The result is that any place on Earth is within less than 24 hrs. of any other place, using the most direct route.

Closely related to time-space compression is cost-space compression, the steady reduction in the cost of moving goods, people, or information between places. For example, the opening of the Erie Canal in 1825 reduced the cost of transport between Buffalo and Albany from \$100 to \$10 and, ultimately, to \$3 per ton. Railroad freight rates in the United States dropped 41% between 1882 and 1900. Between the 1870s and 1950s, improvements in the efficiency of ships reduced the real cost of ocean transport by about 60%. Within the discipline of geography, time-space compression was first theorized in terms of the friction of distance imposed by high transportation costs. Closely associated with the friction of distance was its measurement in terms of travel time and cost, which tend to be more useful in explaining travel patterns than are absolute distances.

In the 1960s, Donald Janelle introduced the notion of time-space convergence, the rate at which places drew closer to one another over time in relative space due to rising transport speeds even as

the absolute distance between them remained constant. One example concerned the changing travel time between Lansing and Detroit, Michigan, which was approximately 1,300 min. by stagecoach in 1840. By the 1870s, with the arrival of the steam locomotive, travel time had been reduced by two thirds, to 180 min.; with the introduction of the automobile, the journey was further reduced to only 80 min. Thus, while the absolute distance between the cities remained the same, the relative distance was reduced by 1,220 min. over 120 yrs., or roughly 10 min./yr. Similarly, between 1800 and 1965, travel times between Boston and New York declined from 4,800 to 300 min., or 27 min./yr. Janelle also introduced the notion of time-space divergence, such as when urban infrastructures become so overloaded with traffic that significant delays occur due to congestion.

In the context of late-20th-century globalization and technological changes, falling transport times created a steadily “shrinking world” that changed the suite of opportunities and constraints faced by places, firms, and individuals. Because markets are shaped by the distances beyond which goods and information cannot circulate in a timely manner, transport and communication costs limit their geographic size. For competitive firms, the steadily declining friction of distance was a significant economic benefit. For other firms, the benefits were not so clear: As transport costs dropped and the spatial division of labor became broader, once protected local industries lost their monopoly status and were forced to compete with other producers in neighboring and then in increasingly distant regions. For individuals, the benefits of time-space compression include increasing mobility to a wider horizon of potential destinations. As the transportation literature demonstrates, mobility levels tend to rise proportionate to income; however, transport times remain essentially stable, indicating that the ability to conquer distance is purchased primarily through increasing velocities.

In the 1960s, the shrinking world was a popular theme among technocrats such as Daniel Bell and Alvin Toffler, who approached the topic from the perspective of “postindustrial” society, the decline of manufacturing, and the rise of an information-based service class. Technocratic views of communication were widely promoted by Marshall McLuhan, whose enormously influential

works portrayed a progression from the limited spatiality of preindustrial societies and orality as the dominant form of communication to the influence of printing, to the global networks of modern telecommunications. Each age, he maintained, saw a dramatic increase in the scale of human extensibility. Technocratic theorizations of time-space compression, informed primarily by technological determinism, tended to present space and time as lying outside of social relations; they ignored or minimized the social inequalities and power relations that the process inevitably entails. This rosy, utopian view, with its impoverished sense of politics and inequality, nonetheless spoke to the profound time-space compression that telecommunications unleashed, and it decisively entered popular consciousness on the subject.

Because it is fundamentally an expression of power, time-space compression is always uneven among groups and places. Time-space compression, thus, does not affect all places or peoples equally. Spatially, this process endlessly generates new geographies of centrality and peripherality, bringing some places closer together and others relatively less so. Generally, the elites tend to enjoy the earliest and often the greatest advantages from reduced costs and transmission times of transportation and communications. Time-space compression is intimately associated with the ways in which capitalism generates new geographies over time. Globally, cheaper, more efficient modes of transport widened the range over which goods could be shipped profitably, allowing regions and countries to realize a comparative advantage and stimulating large-scale production and an increasingly internationalized geographic division of labor.

Within countries, transportation improvements contributed to changing patterns of urban accessibility. Cities in the industrialized world grew from compact walking and horsecar cities (pre-1800 to 1890) to electric streetcar cities (1890–1920) and, finally, to dispersed automobile cities in the recreational automobile era (1920–1945), the freeway era (1945–1970), the edge city era (1970–1990), and the exurban era (1990 to present).

Contemporary Time-Space Compression

Telecommunications represent the latest, and perhaps most profound, in the long series of chapters

of time-space compression, effectively reducing the communication time between places to zero. The telegraph in the 19th century, for example, connected the global economy's expanding networks almost instantaneously, allowing news to travel at the speed of light, reducing uncertainty for producers, allowing multi-establishment firms to connect headquarters and branch plants, and allowing markets to expand over ever larger spatial domains. The telephone had similar effects throughout the 20th century, and declines in the cost of telephone service generated considerable cost-space compression, with multiple economic, social, and psychological impacts. Starting in the 1980s with the microelectronics revolution, a worldwide skein of fiber-optic lines has come to form the nervous system of the international financial economy, creating the time-space compression of the flexible, post-Fordist, digitized global economy. Electronic funds transfer systems allow financial institutions to switch vast sums of capital from one place to another instantaneously, in the process arbitraging interest rate differentials, speculating in foreign exchange, and investing or disinvesting in a wide variety of instruments in a diverse array of markets. The Internet represents another dimension of this process. Connecting roughly 1.7 billion people in 2009, the interlinked series of computers that comprise the Internet and the World Wide Web allow almost instantaneous time-space compression. Yet even within the best connected of global cities, for example, there are substantial pockets of "off-line" poverty.

Globally, in a shrinking world, distant strangers become less and less distant or strange. David Harvey attributes the growth of postmodern culture—the fragmented set of discourses emphasizing difference and heterogeneity that flourished in the late 20th century—to the compression unleashed by digitized, globalized time-space compression. It is critical to emphasize that time-space compression is not inherently beneficial to all those affected but results in uneven gains and sometimes losses: For some, it represents a rise in efficiency and an increased ability to master space; for others, it consists of a loss of control as their worlds are enveloped within wider divisions of labor controlled by powerful strangers. Because the structures of time and space are wrapped up with relations of power,

domination, and subordination, the shrinking world does not shrink in the same way or equally for everyone; time-space compressions always simultaneously empower and disempower different social groups. Often the process accentuates existing social inequalities, as when, for example, the wealthy deploy new technologies that leave the poor further behind. Indeed, time-space compression for some may be time-space expansion for others.

T-IN-O MAPS

The label T-in-O maps, or simply "T-O maps," is the modern name given to a simple world map found in a variety of sources during the Middle Ages. They appear as explicit graphics (i.e., diagrams made with circles and straight lines with

Figure 1 Model of a typical T-in-O map. Common in medieval Europe, T-in-O maps divided the known world into three continents along biblical lines.

Source: Author.

names attached), as the structure underlying far more complex maps (e.g., the Hereford *mappa mundi* has one as its underlying structure for the continental landmasses), and as symbolic representations of the earthly, human, sublunar world (e.g., it inspired the “royal orb” that is or was part of the regalia of European royalty, and in that form, it can be found linked to many Christian statues). In form, the T-O map is a circle with its horizontal diameter marked and with a radius perpendicular to that diameter running down to the lowest point on the circle. The diagram looks like a “T” inscribed in an “O,” hence its modern name. East is at the top of the circle. The upper half represents Asia, the lower quarters Europe (*left*) and Africa (*right*). The outer circle is the Ocean; the left radius represents the Danube (although it is commonly misidentified as the Don); the right radius represents the Nile and the lower radius, the Mediterranean. It portrays the whole of the inhabited world, in the northern temperate zone, as it was known to the Europeans.

Other details are often added to the basic map. There is a more elaborate form showing the Danube’s mouth; often the continents are shown with

the names of the children of Noah (see Genesis 10) from whom the African (from Ham/Cham), Asian (from Shem/Sem), and European (from Japhet) nations were believed to have descended; and often one or two local details (e.g., the Pillars of Hercules [Gibraltar] or the British Isles) are shown.

The map has to be read in conjunction with other geographical diagrams to appreciate it fully. The most important of these other drawings is the zonal map, which has a torrid zone at the equator, frigid zones at the poles (both uninhabitable), and between them a northern temperate zone (which is the area covered by the T-in-O map) and a southern temperate zone, in which it was assumed that there was a corresponding landmass but there was a debate as to whether or not it was inhabited (the antipodes were its putative inhabitants). When this consideration is taken into account, the T-in-O map can be seen not as that of a “flat Earth” but as an attempt to portray lands on a sphere as seen from a great distance. As such, it embodies elements of an orthographic projection; however, insofar as it has the eastern end of the Mediterranean at its center and the ocean as the circumference, it has elements of an oblique azimuthal projection. It was this aspect of this map, when read in conjunction with certain biblical passage (e.g., Ezekiel 5:5) that led to the practice of placing Jerusalem at the center of many medieval maps.

The origins of the map lie in antiquity. In Homer, the shield of Achilles had a depiction of Earth, and around its edge ran the “Ocean river,” while errors in orientation in Roman sources show that they thought of their lands in a way remarkably similar to the way they are laid out in the T-in-O map. Likewise, Luke’s account in the Acts of the Apostles of the travels of St. Paul are far easier to follow on a T-in-O map than on the modern maps now found in bibles. However, the earliest evidence of the map is to be found in the writings of Isidore of Seville (ca. AD 560–636). Evidence points to the copyists having imported the map from Isidore to give clarity to the descriptions. Isidore produced two distinct forms of the map: The simpler one is just the T in the O with the continents’ names found in his encyclopedia, the *Etymologiae*; the more complex map is found in his treatise on the material creation, the *De natura rerum*, which contains additional details of the mouths of the Nile and the Danube, while the linear text mentions other geographical information

that occasionally was depicted on the map (e.g., the cardinal directions placed outside the O). These two forms were subsequently imported into many other texts as distinct items of common knowledge (e.g., Lucretius's textbook *De natura rerum* [*On the Nature of Things*]). Also, the two forms were often merged, or merged and combined with other "facts" of geography, such as that Paradise was in the east.

There is hardly a Western European map from before the 15th century that is not influenced by the T-in-O form. It fitted with the experience and travels of people from that region (e.g., one can travel across Europe using a 12th-century map by Giraldus Cambrensis, which is based on a T-in-O map), it conformed to all their classical authorities (e.g., it helped in reading Sallust), and it supported the image of the world they used in reading the Bible (e.g., the division of the Earth to Noah's sons or the travels of Paul). It finally disappeared from use with the revival of interest in Ptolemy's *Geography* and its very different world map.

TOBLER, WALDO (1930–)

Waldo R. Tobler is a geographer and a cartographer who has done much to expand ideas about what can be mapped and how. He was closely associated with the quantitative revolution in the 1960s, leading the move to computer mapping, developing new map projections, and applying mathematical techniques to practical questions. His interests led him to consider issues in geographical information science, and he was part of the Santa Barbara team in the National Center for Geographic Information and Analysis.

Tobler was born in 1930 in Portland, Oregon, to a Swiss family. His father was the Swiss consul, with responsibility for the Pacific Northwest. Tobler completed his undergraduate degree at the University of Washington, having drifted into geography because he enjoyed reading maps. He proceeded to a master's degree, specializing in cartography. He left Washington and returned after 2 yrs. (years) to do his doctorate. He was at the University of Washington in the late 1950s, at the same time as many of the future leaders of the quantitative revolution. Geographer William Garrison was a junior faculty member, and the graduate students included Brian Berry, William Bunge, Michael Dacey, Arthur Getis, Duane Marble, and Richard Morrill. Tobler says that he "learned just as much or more from fellow graduate students as from the faculty." Graduate students were encouraged to learn computing as well as to take courses in mathematics and econometrics; ideas from such courses could often be applied in cartography. His PhD dissertation, *Map Transformations of Geographic Space*, developed new ways of mapping based on time or cost distances and investigated the mathematical basis of cartograms.

After leaving the University of Washington, Tobler became a faculty member at the University of Michigan, where he worked for 16 yrs., moving to the University of California, Santa Barbara, in 1977. Although still primarily a cartographer, he kept up his interests in many aspects of spatial analysis. His work on migration is distinctive. While most geographers modeling human behavior do so using statistics, Tobler uses other branches of mathematics, such as vector analysis and partial differential equations. He was also a leader in the development of animated maps, for example, the

film of the spatial development of Detroit. His write-up for this “computer movie,” appearing in 1970, included his most quoted aphorism, now known as Tobler’s first law of geography: “Everything is related to everything else, but near things are more related than distant things.” This claim has attracted much attention. Decades later, the Association of American Geographers held a symposium on Tobler’s first law, the proceedings of which were published in the *Annals of the Association of American Geographers* in 2004.

TOMLINSON, ROGER (1933–)

Roger Tomlinson played a key role in establishing geographic information systems (GIS) from their earliest years. He is one of the very few who merit the title “father of GIS.”

Born in Cambridge, Britain, Tomlinson was a flying officer in the Royal Air Force before attending Nottingham University. He obtained an honors degree in geography (1957) and then moved to Canada for another BSc in geology at Acadia University in Nova Scotia (1960). He continued with an MSc in geography at McGill (1961), while starting work at Spartan Air Services on various forms of terrain evaluation. This work led him to investigate the use of digital computers to store and analyze geographic information. In the 1960s, he

joined the Canadian government as head of the development program for an information system to be known as the Canada geographic information system (CGIS). While others around the world began to use GIS terminology at about the same time, CGIS was conceived at a continent-spanning scale from the start. His paper on CGIS in 1968, presented in Australia, may have been the first use of the term *GIS* in a reviewed publication. The analytical objectives of CGIS were as challenging as the sheer effort in digitizing four map layers across Canada at a scale of 1:250,000.

He obtained a PhD in 1974, writing a thesis that described CGIS in detail. Tomlinson’s vision of GIS attracted international attention during the 12-year period in which he chaired the Commission on Geographical Data Sensing and Processing of the International Geographical Union. Since the early 1970s, Tomlinson has worked as a consultant to government and industry around the world. His important achievements come largely from the critical appraisal of actual needs and his commitment to pushing the technology forward. At the critical juncture when the commercial software sector was emerging (around 1980), he and his associates rejected all tenders for the Saskatchewan Natural Resources project. This action held the developers to high standards that were not met until a few years later. In this role, as much as at CGIS, he directed the future of what became the GIS industry and practice.

Tomlinson has been a tireless campaigner for geographic awareness and geography as a discipline and a profession. He has received many awards for service to geography and GIS and was appointed to the Order of Canada in 2001.

TOPOLOGICAL RELATIONSHIPS

Topological relationships are the qualitative relationships of geographic objects that are not affected by continuous distortion, such as translation, rotation, scale, or skew. These relationships are said to exhibit a property known as topological invariant. In other words, topological relationships describe the spatial interrelations among geographic objects, and how they are linked together, without reference to their geographic locations, dimensions, or orientations. Some examples of topological relationships are (a) *touch*—a point touches a line (e.g., a bridge on a river); (b) *cross*—a line crosses another line (e.g., a road across a river); and (c) *within*—a region is completely contained by the boundaries of another region (e.g., an island in a lake). In addition to topological relationships, geographic objects can also have projective relationships, such as orientation (left or right), and metric relationships, such as distance, which can be measured quantitatively. These geometric

relationships are fundamental predicates for geographic representation and reasoning.

The definition of topological relationships derives from how geographic objects are understood and represented, or, more broadly, from ontology. One way to define topological relationships is Egenhofer and Herring's nine-intersection scheme, which uses discrete points, lines, and regions to represent the geometries of geographic objects. The scheme uses the interiors, boundaries, and exteriors of two geometric objects to construct a 3×3 matrix, in which every entry denotes whether the intersection of the two object parts is an empty set or not, tested under the topologically invariant condition. Each distinctive set of nine intersections represents a different topological relationship. Out of the 512 (2^9) possible combinations of the 3×3 matrix, the nine-intersection scheme identifies, for example, 8 relationships between two regions with connected boundaries (i.e., no holes or disjointed parts) and 33 relationships between two simple lines (i.e., lines without branches). Some topological relationships are illustrated in Figure 1.

Figure 1 Examples of topological relationships

Source: Adapted from Egenhofer, M. J., & Herring, J. R. (1991). *Categorizing binary topological relations between regions, lines, and points in geographic databases* (Technical Report No. 91-7). Santa Barbara: University of California, National Center for Geographic Information and Analysis.

The nine-intersection scheme provides a formal definition of topological relationships, and as part of the Open Geospatial Consortium specifications and ISO/TC 211 standard, some of the relationships have been implemented in commercial geographic information systems and spatial database systems to formulate qualitative queries about the connection properties of spatial objects. Its reasoning framework facilitates finding new relationships from a set of geographic objects. As the geometric representations of geographic objects become more complex and additional object properties, such as nonplanar geometry, movements of objects, or vagueness of their boundaries, are considered, the task of defining the topological relationships becomes more difficult and sometimes intractable. Many topological relationships identified in the framework have no corresponding natural-language equivalents, making them not applicable in qualitative spatial reasoning that is based on the semantics of natural languages. Given these practical purposes and concerns, topological relationships have become a topic of interdisciplinary research involving the fields of geography, geographic information science, linguistics, artificial intelligence, and cognitive science.

TOPONYMY

Toponymy is a discipline that developed in the linguistic sciences. It studies the proper names of places from different points of view and according

to different perspectives. This research seeks to find the essence of proper names through their evolution from a single instance of a common name to a final proper name. In the final situation, the proper name is a classically opaque “sign” in which the sound (or the grapheme, in its written form) cannot be directly linked by the user to a meaning, inasmuch as the name has lost its direct link to the designated place. For this reason, the study moves in the direction of etymology, which investigates the semantic origins of names. Research into the etymological origins of a name presupposes that the researcher has knowledge of the language or languages from which the common name emerged and of the forms that this name took in the various stages of its evolution. Historical testimonies are thus fundamental instruments in toponymy research, in particular archival documents for historical names and field research through inquiry with witnesses and direct users of the name.

These characteristics place toponymy at the crossroads of disciplines that are to a greater or lesser degree linked; among these, the most closely linked are the history of populations, ancient languages, and the historical and geographical evolution of languages. The links with geography are strong: Toponymy is a fundamental part of geographic study inasmuch as it studies the names of geographic entities.

Links With Geography

It is important to remember that by its very nature (viz., its focus on the longevity and conservation of original traits), the study of the names of places represents an important part of various aspects of geography inasmuch as the name of a place is testimony to its characteristics and modifications of its territory. Aspects that are particularly enhanced include the spread of different types of flora and the identification of territorial characteristics (physical geography, territorial conformity, spread of fauna, aspects of the territory as interpreted by the population that inhabits it, etc.).

Furthermore, toponymy also sheds light on aspects linked to the economic and social geography of a specific place, for example, the institutional and organizational aspects of territories. From a historical perspective, the analysis of

names can contribute to tracing the history of geographic settlements and migration. Finally, toponymy represents a fundamental part of cartography inasmuch as it can contribute to the identification of names to be written on maps and the most appropriate form of their transcription.

To realize its intentions, toponymy proceeds through the systematic collection of names of places. These names are then analyzed with the intent of making generalizations through observation. Parallel to this approach, other study directions are involved in researching the spread and characteristics of toponymic types in detail.

New Applications

In addition to historical and diachronic investigations, toponymy developed applications that are less strongly linked to its founding discipline. Inherent in this direction is the inquiry into the formal choice of toponyms, the relationships between the name of a place and the community that inhabits it, sociological and legal statutes pertaining to the name, the creation of new names, the replacement of old names, and the links between names of places and people. In this way, toponymy has developed links with disciplines such as sociology, sociolinguistics, cultural history, ethnography, anthropology, philosophy, urban studies, political science, and literary criticism.

Particular attention is given to the definition of a place name inasmuch as it can assume vastly different forms: For example, it can be indicative of a field or a small holding, a settlement, a city, a nation, a continent, water courses, mountain elevations, buildings, and so on. Over time, toponymy has developed research into aspects related to the nomenclature of common geographic names and, in so doing, closely collaborated with geography. In this regard, a recent direction of analysis strives to observe tendencies related to the interlinguistic aspects of a name: translations of names, the use of names in their original form in a different language, and so forth.

TOPOPHILIA

Topophilia lies at the intersection of geography and environmental psychology, describing the human emotional experience of the physical environment, including sensory perceptions, attitudes toward nature, and valuations of specific components or composites of the landscape. Topophilia generally implies an affection for specific places, but the term involves a spectrum of responses that may include disaffecting experiences for disliked or less preferred locations. Hence, since its original expression by the geographer Yi-Fu Tuan in the mid 1970s, the meaning of *topophilia* has evolved, and additional related terminologies have emerged. For example, the term *topophobia* has been used to describe the fear of specific geographical features. Furthermore, it is difficult to disentangle topophilia and topophobia—which are often associated with the nonliving components of nature—from the human emotional response to the living components of nature, which is captured separately by the terms *biophilia* and *biophobia*.

When confronted with images or direct experiences of different landscapes such as rain forests, sandy deserts, meadows, ocean fronts, and urban landscapes, most individuals do not find it difficult to declare ranked preferences, although they may not be able to articulate the rationale for such preferences. Attempts to deconstruct responses to specific components of natural or built landscapes are rare, but recent research to elucidate topophilia have revealed four domains within which human emotional attachment or detachment from the physical environment can be categorized: (1) ecological diversity, including the natural composition of vegetation, animals, and insects and the presence of water bodies;

(2) synesthetic tendency, described as the comingling of the senses of sight, smell, texture, and temperature; (3) cognitive challenge, including geometrical shapes, landscape complexity, and opportunities for solitude and contemplation; and (4) familiarity, according to the level of comfort experienced by repeated exposure to the same or similar places.

Understanding the determinants of individual or group preferences for specific components of natural and urban landscapes has been proposed for facilitating the design of restorative environments such as hospital landscapes, where residents hope to recover from diseases, or urban landscapes, where the pressures of daily survival can contribute to subnormal mental health conditions. Additional research may assess variations in individual preferences based on community expressions of toponophilia.

visible as a condensation funnel or by the dust and other debris incorporated into the rotation. About 1,500 tornadoes are recorded annually around the middle latitudes of Earth, and they typically cause 100 to 300 deaths.

Regional Occurrences and Frequencies

Tornadoes occur in many regions of the world but are most frequent in the middle latitudes, especially in the Central and Southern United States, but with the most loss of life and livelihood occurring in Central Bangladesh. The United States records about 1,100 tornadoes annually. This count has doubled since the 1950s, but the increase is thought to be due to better reporting and recording of tornadoes rather than an actual increase in the number of tornadoes. Canada records about 60 tornadoes annually; the United Kingdom and Australia each about 30; Germany, France, and Italy each about 20; and Argentina and Bangladesh each about 10. A substantial number of tornadoes also occur in other European countries and in India, South Africa, China, Japan, and New Zealand. Tornadoes are undercounted in many countries because small tornadoes are not observed and recorded. The number of tornadoes seems to increase in these regions as reporting efficiency and record keeping improve.

The occurrence of tornadoes is restricted to the regions where conditions are favorable for their formation. Thus, they are most common in the middle latitudes, where a contrast of air masses, vertical wind shear, instability, a strong jet stream, and strong cyclonic storms and fronts most commonly occur. Although tornadoes may occur more frequently over flat terrain, they are known to occur in hilly terrain and to cross large mountain ranges and descend into deep valleys. No terrain is “protected” from tornadoes.

Seasonal patterns of tornado frequency exist, with a spring and summer peak in the United States. The occurrence of tornadoes generally coincides with the annual peak in thunderstorm frequency. On the diurnal scale, tornadoes most often form during the afternoon and evening hours when atmospheric instability is greatest and thunderstorms are most violent.

TORNADOES

A tornado is a violently rotating column of air in contact with the ground. It usually forms under a cumulonimbus (thunderstorm) cloud and is

Conditions for Formation

Tornadoes are classified into two broad categories, supercell tornadoes and nonsupercell tornadoes. A supercell tornado forms within supercell thunderstorms that contain mesocyclones in the middle levels of the atmosphere. Mesocyclones are rotating updrafts that may persist for several hours. They form in a moist, unstable environment with strong vertical wind shear. A supercell thunderstorm may produce several tornadoes, called a “tornado family,” with one tornado forming as the previous one dissipates. Rotation develops in the thunderstorm updraft due to the change of wind speed and wind direction with height above the ground, called vertical wind shear. This wind shear causes horizontal vorticity. Stronger winds aloft cause a tilting and stretching of this horizontal vorticity, and this results in a rotating cloud with vertical vorticity, the mesocyclone.

Not all supercell thunderstorms produce a tornado. The mechanisms that create rotation at ground level, that is, a tornado, are poorly understood. Large vertical vorticity must arise at the ground. This may develop when horizontal vorticity near the ground is tilted into a vertical rotation. Vertical vorticity near the ground may also arise through the transfer of vertical vorticity toward the ground by a rear-flank downdraft from the mesocyclone. The rear-flank downdraft is dry air that descends from midlevels in the atmosphere and wraps around the back of a mesocyclone. The rear-flank downdraft may tilt horizontal vorticity into vertical vorticity, transfer vertical vorticity from the mesocyclone toward the ground, or enhance existing vertical vorticity near the ground, and any of these may lead to a tornado.

Nonsupercell tornadoes occur with the growth stage of a parent cloud and originate from near-ground convergence and rotation, or vertical vorticity, in the lower layers of the atmosphere. Although they are dangerous, they tend to be smaller and weaker than supercell tornadoes. Gustnadoes and landspouts are examples of nonsupercell tornadoes. A gustnado forms along a gust front or other storm outflow boundaries and is visible as a swirl of dust or debris. A landspout appears as a long, narrow rotation, similar to the

waterspouts seen along the Florida coasts, and does not require a preexisting boundary.

A waterspout is a tornado over water. These include supercell tornadoes that form over land and then pass over a body of water. More commonly, however, a waterspout forms over warm waters as a nonsupercell tornado with low-level convergence. They are most common over the waters of the Florida Keys but also occur with cold air advection across the warmer waters of the North American Great Lakes and elsewhere.

Tornadoes may occur over land in association with tropical cyclones (hurricanes). Tornadoes that form in rain bands more than 200 km (kilometers) from the cyclone center are called “outer-region” tornadoes and may touch down near the coast well before landfall of the tropical cyclone. They show a diurnal cycle, with most occurring during the afternoon. Inner-region tornadoes, within 200 km of the center, occur less than 12 hours prior to landfall and tend to be weaker, with no diurnal cycle. About 60% of tornadoes associated with tropical cyclones occur within 100 km of the coast, but the threat persists 2 to 3 days after landfall and extends 400 km inland and 500 km from the cyclone center.

Most tornadoes rotate cyclonically (counterclockwise) due to the direction of rotation in the parent thunderstorm cloud. Some tornadoes have smaller secondary rotations, called suction vortices, within their broader rotation. The suction vortices are cycloidal swaths of stronger winds and create local gradations of wind damage caused by tornadoes.

Damage and Casualties

Damage and casualties result from the strong winds in tornadoes and the impacts of the debris carried in those winds. Damage to buildings and other structures increases with stronger wind speeds but depends also on the strength and quality of the construction and the anchorage of the building to the ground. These characteristics of building quality vary geographically according to traditions, customs, and wealth. Contrary to popular notions, buildings do not “explode” from differences in pressure inside and outside the tornado but from the forces exerted by the winds on the walls and roofs.

The first tornado captured by the NSSL Doppler radar and NSSL chase personnel, Union City, Oklahoma, 1973. The tornado is here in its early stage of formation.

Source: NOAA Photo Library, NOAA Central Library; OAR/ERL/National Severe Storms Laboratory (NSSL).

Wind damage begins with the roofing materials, gutters, windows, awnings, and canopies. These destroyed materials are then carried in the wind and, by their impacts, cause additional damage to structures downwind. With stronger winds, sections of the roof are lifted from the structure, and exterior walls collapse. These building failures can be mitigated by making strong attachments between the roof and the walls that will resist the uplifting forces of the wind. At the higher wind speeds, which are rare, structures are totally destroyed, and all interior walls collapse.

The Enhanced Fujita Scale is used in the United States to rank the intensity of tornadoes and to relate the damage to the estimated wind speeds (e.g., a 3-second gust at 10 m [meters] height) over a range from EF0 (65–85 mph [miles per hour]) to EF5 (more than 200 mph). In Britain, a similar scale for calculating tornado wind speed and damage, the TORRO Scale (Tornado and Storm Research Organisation), is used. Wind

speeds of about 75 mph break large branches from trees, and winds of 100 mph cause trees to snap or be uprooted. A typical family home in the United States will sustain roof damage at about 80 mph, but exterior walls remain intact up to about 130 mph (EF2). Mobile homes, where most tornado-related deaths occur in the United States, are rolled over and destroyed at wind speeds of about 100 mph (EF1). Apartments and condominiums lose roof covering at 100 mph, but walls remain intact to about 155 mph (EF3). Large retail buildings suffer the loss of roof and walls at about 135 mph. About 14% of tropical cyclone tornadoes are ranked EF2 or stronger on the Enhanced Fujita Scale, with maximum winds over 110 mph.

Injuries and deaths occur when people are exposed to the high winds and flying debris of the tornado. Some are injured in collapsed buildings, while others are caught outdoors and struck by debris or carried some distance. The very young

and the elderly suffer more deaths and injuries than youth and middle-aged persons.

Weak structures are easily collapsed by the wind or penetrated by debris and offer little protection to the occupants during a tornado. In the United States, about 45% of deaths due to tornadoes occur among residents of mobile homes, yet only 7% of the population resides in these structures. A stronger building offers more protection, especially if people seek a small interior room for shelter and stay away from windows. An underground shelter or basement is the safest location during a tornado. A vehicle may offer more protection than being outdoors or in a mobile home, but motorists should seek shelter in a sturdy building during a tornado. Death tolls from tornadoes decreased during the 20th century in the United States, from about 300 deaths annually to about 50 per year, due to better warning and communication systems, stronger buildings, and education about the risks and proper shelter.

The deadliest tornadoes in recent decades have occurred in Bangladesh, where 1,300 people were killed by a tornado on April 25, 1989, and 700 were killed on May 13, 1996. The deadliest tornado in the United States was on March 18, 1925, when 695 people were killed in Missouri, Illinois, and Indiana.

Injuries and deaths can be reduced by storm surveillance and early-warning systems. Government weather services can give a warning 5 to 15 minutes before a tornado strikes by receiving a report of a tornado on the ground or by observing strong rotation in a cloud with Doppler radar. The warning and information about the storm are disseminated to the public by radio, television, neighborhood sirens, or other electronic devices. Risks of injury are reduced if persons in the path of the storm become aware of the warning and take immediate action to move to the safest shelter. Where personal shelters, such as a sturdy house, basement, or underground storm shelter, are not available, community shelters can be provided to allow many people to take temporary refuge from the storm. These may be functions of wealth, education, class, race and ethnicity, gender, age, disability, and other social factors.

TOURISM

Tourism is defined as travel to a place outside the usual residential environment, involving a stay of at least one night but no more than 1 year, with varying motivations, such as business, pleasure, visits to friends and relatives (VFR), and education. It is one of the world's largest industries. Tourism has long been of interest to geographers,

Tourism in Switzerland: Hotel Wetterhorn

given its spatial, temporal, and activity patterns and given its major economic and environmental impacts, ranging from the local to the global.

Geographers have been influential in developing conceptual models for explaining tourism development. Some of the most important models are resort morphology, the tourist-historic city, and the tourist area cycle. Douglas Pearce's work on resort morphology has helped explain the resort's particular urban form and its evolution in response to new recreational demands. Pearce found that many older beach resorts first developed around a traditional waterfront; later, parallel developments, including a road or highway, high-end accommodation and retail, and interior residential zones, were built as one moved inland. Given environmental degradation and traffic hazards with this traditional resort model, newer shore resorts have increasingly integrated accommodations with the sea via yacht moorings. Likewise, modern integrated ski resorts similarly

physically integrate the snow front (slopes and uphill facilities) with concentrated resort buildings. As with new urbanist developments, these new resort models allow for greater integration of accommodations and activities, reduce the amount of land developed, and promote more efficient service provision (e.g., heating, water, sewage). However, equity issues have arisen since integrated development generally favors a single developer, often from distant metropolitan areas and having the needed capital and technical expertise, over smaller local or regional entities.

Another key model in tourism geography is the tourist-historic city model, which represents the fusion of a tourist city with a historic one. The tourist-historic city has attractions, dining services/restaurants, and accommodations in the historic core. Tourists' action spaces and impacts tend to be concentrated within a small portion of the entire city. This model, which was based on medium-sized, older historic cities in Europe, has

Alpine and lake landscapes for tourism, Switzerland

Source: Barbara Peacock.

been modified to explain tourism in other parts of the world. In settlements of the American West, historic and reconstructed tourist attractions and accommodations can be found in the equivalent historic cores, which are the old central business districts containing train stations. However, with the dominance of the automobile, a newer, secondary concentration of lodging and dining services for tourists can be found along interstate highways.

The tourist area cycle model developed by the geographer Richard Butler has influenced and spurred much research, application, and debate. The underlying concept, which is based on the

product cycle, is that tourist areas, their attractions, and the number and type of their tourists evolve over time. Tourist areas move through the following stages: (a) *exploration*, in which there are a small number of tourists who are attracted to unique natural and cultural-historical features, use the local facilities, and have high contact with the local residents; (b) *involvement*, with increasing visitation; (c) *development*, in which the number of tourists during peak seasons exceeds the local population and locally developed infrastructure and original attractions are supplemented and increasingly supplanted by human-made attractions and facilities developed by external entities;

Figure 1 Tourist area cycle model

Source: Drawn by author, based on Butler, R. (1980). The concept of a tourist area cycle of evolution: Implication for management of resources. *Canadian Geographer*, 24(1), 5–12.

(d) *consolidation*, in which tourism is a major component of the economy and thus marketing and advertising efforts increase to expand the visitors' season and market area, particularly as the rate of increase in visitation is declining (while the total number of visitors continues to increase); and (e) *stagnation*, in which the peak number of visitors and carrying capacity levels are reached, natural and cultural attractions are superseded by created ones, and the less fashionable area relies on repeat and convention visitors. At this point, tourist areas can continue to stagnate, or they may move into a stage of *decline*, with reduced visitation and number of tourist facilities but often with increased permanent settlement or retirement. Alternately, they may undergo *rejuvenation* by completely changing the tourist attractions or by

capitalizing on previously untapped resources. While this model has been much examined and debated regarding its fit to real places, it has important implications for planning, as it confronts the assumption that tourist areas are unchanging and will always attract an increasing number of visitors. Butler notes that the competitiveness of tourist areas could be sustained longer if proactive policies were enacted to maintain development within capacity limits.

Geographers have also played an important role in infusing critical perspectives into tourism research. In his seminal 1991 article integrating critical theory and political economy into the study of tourism, "Tourism, Capital, and Place: Towards a Critical Geography," Stephen Britton called attention to the fact that tourism is an

Rejuvenating the city with tourism and entertainment: Movement 2009, Detroit's electronic music festival, with GM headquarters in the background

Source: Author.

important avenue of capitalist accumulation. Places are symbolically marketed as desirable experiences that impart status to those visiting or consuming them. As such, Britton argued that geographic theorization of tourism requires consideration of how social representations and materiality of leisure and touristic experiences and places are incorporated and commodified in the accumulation process. As part of viewing tourism as a mechanism for capital accumulation, geographers have looked at power relations and issues such as social equity, identity, authenticity, and social attachment to space as these are

manifested in travel and tourism. Critical political economy/ecology perspectives on tourism have also been used to examine topics such as imbalances in consumption, impacts on host communities, environmental justice, and sustainable development. The political ecology framework is particularly suited to looking at the impacts of nature protection for economic development and struggles to maintain customary land use, livelihoods, and access to natural resources.

Given economic restructuring and the recent crises in capitalism, Britton also argued that the geographical analysis of tourism could contribute to the analysis of territorial competition and the rejuvenation of depressed regional economies. Britton's call is relevant to the ongoing challenges to reposition deindustrialized downtown areas for consumptive activities such as leisure and tourism and for corporate services. Cities worldwide have developed tourist entertainment districts that typically contain an atrium hotel, a festival mall with restaurants and bars, a convention center, a restored historic neighborhood, a domed stadium, an aquarium, new office towers, a redeveloped waterfront, and casinos, which attract tourists, daytime

professionals, and suburban evening and weekend visitors. When such tourist entertainment districts are developed in areas surrounded by high crime, poverty, or urban decay, they may be secured and isolated "tourist bubbles." Such tourist entertainment districts and bubbles often are sites for festivals and spectacles to attract suburban visitors as well as tourists in the ongoing territorial competition. For instance, Detroit, which has experienced the loss of industrial facilities, jobs, and population since the 1950s, has developed a downtown tourist entertainment district anchored by two new sports stadia, has landed mega sporting events, and has

Urban festivals and tourism; main stage at Movement 2009, Detroit's electronic music festival

Source: Author.

hosted festivals (e.g., Movement, Detroit's electronic music festival, which draws a regional, national, and international audience) to foster its claims of being a world-class city. With the recent bankruptcies of Chrysler and General Motors, Mayor David Bing stressed the city's culture and entertainment (sports, gaming, music) as a means of keeping the city competitive for population, jobs, investment, and industries such as tourism, which are key for its postautomotive future.

In addition to flows of capital, tourism can be investigated in terms of its relation to migration tied to broader economic and social changes. Volatile labor markets since the 1970s in more developed countries, changing income streams (e.g., pensions, capital accumulation through property), and aging of those societies have spurred early retirement and retirement migration to rural areas. Rural lands in advanced industrialized

countries have increasingly shifted from a production orientation to a consumption one. The amenity-based, tourism and housing countryside appeals to those romanticizing nature, the past, and the rural; amenity seekers; second-home owners; and/or entrepreneurs cognizant of the marketable attributes of the rural landscape. In addition to rural, domestic migration, others may choose to migrate overseas to retirement communities or for lifestyle and business prospects (e.g., British immigrants to the Costa del Sol serving travelers from their country of origin). For others, the globalization of labor markets has opened up doors for skilled labor/expatriates in developing countries. Other forms of tourism-related migration include VFR and seasonal labor flows differentiated by ethnicity, race, and gender.

While tourism has been a way to address the challenges resulting from the shift from Fordism

to post-Fordism and from production to consumption, tourism production itself has remained remarkably varied. The travel industry has provided post-Fordist, individually tailored experiences (e.g., specialized luxury ecotourism excursions). However, in neo-Fordist tourism, which is marked by industrial concentration of airlines, transnational hotels, cruise companies, tour operators, and computerized booking systems and by high sales volume, standardized vacation packages appealing to a mass audience continue to be provided. Neo-Fordist tourism employment consists of both highly skilled, well-paid permanent professionals and flexible, low-wage seasonal labor. At the same time, the travel and tourism industry also includes pre-Fordist or artisanal businesses such as bed and breakfasts. Thus, given the coexistence of different production systems in both time and space, there has not been a clear shift from Fordism to post-Fordism in the tourism industry.

Tourism can benefit the discipline of geography. Tourism geography education can increase course enrollments and majors in departments that develop tourism majors or concentrations. It can raise the discipline's visibility as geographers bring content on sustainability, cultures, heritage, and geospatial analysis to interdisciplinary tourism and hospitality programs. Research on tourism can contribute to applied and theoretical developments in geography. For instance, tourism provides an ideal lens for investigating transnational spaces, as it highlights multiple ties and interactions linking people or institutions across borders of nation-states (i.e., migration of tourism workers, transnational business structures, and tourists and local residents reshaping identity, landscape, and social networks). Tourism can aid in conceptualizing the flexibility and fluidity of capital, complex ownership, and globalization. Likewise, tourism can help in the theorization of border spaces, which can be deterrents or attractions but also can be "non-places" or "in-between spaces." Cross-border cooperation, which ties into geopolitics, peace, and international treaties, is important to tourism and can be investigated in terms of how it varies by scale (i.e., being greater at the interlocal and international scales than at the larger global, regional, and bilateral scales). One major research outlet has been the journal *Tourism Geographies*. Given the

geographical aspects of tourism, including how it transforms the environments of destinations, entails movement over space, and provides a distinctive way for people to relate to the world, *Tourism Geographies* would incorporate these aspects through geography's unique synthesis of the social and physical sciences in understanding places, regions, and the world. Geographers continue to contribute to research on topics as varied as indigenous tourism, amenity/retirement migration, mountain tourism, mobilities, protected areas, tourism and climate change, heritage tourism, tourism landscapes, and tourism planning. Geography and tourism will continue to be mutually enhancing in the future.

TOWNSHIP AND RANGE SYSTEM

The U.S. Public Land Survey System is a township and range pattern of land division that was imposed across the United States west of Pennsylvania's western boundary in territory deemed "public domain" as the early nation expanded to the Pacific Ocean. It is the foundation of a cadastral survey that defines boundaries for land ownership. It forms a gargantuan checkerboard of surveyed grid-squares defining millions of parcels of land that served literally as the framework for colonizing and developing the vast new country. Reminiscent of Roman land centuriation, at least in its geometry, the American system was first proposed by Thomas Jefferson, who saw it as the most democratic way to create a great agrarian commonwealth of independent farmers based on freehold land ownership. Neither he nor anyone else at the time foresaw the rugged Western terrain that the system would confront.

The system had its origin in the Land Ordinance of 1785, which provided for the systematic survey and monumentation of public domain lands, and the Northwest Ordinance of 1787, which established a rectangular survey system designed to sell and grant federal lands to private owners. From a modest beginning in the Seven Ranges area of Eastern Ohio, the system grew to encompass most of the nation's territory and to stamp the American landscape with its unique, mechanistic imprint of seeming dominance over the continent's natural environment. The chief exclusions from this federal system of land division are portions of Ohio that were surveyed and alienated from the public domain before the system was fully institutionalized; land in Texas, which remained under state control as a condition of annexation; lands granted to private interests under Spanish, French, and Mexican dominion prior to American sovereignty; Native American reservations; and certain high-mountain areas in the Far West that have never been officially subdivided.

Earth's curvature required that the extension of the system be tied to periodic benchmarks of longitude and latitude, known as prime meridians, and baselines defined for specific regions, so that the theoretically flat two-dimensional grid

pattern could be laid out on the spherical surface with necessary corrections made at intervals. The basic areal unit is the survey *township*, a square 6 miles on each side, comprising 36 square miles, each square-mile subunit (640 acres in area) being called a *section*. Within townships, sections are numbered sequentially from the northeast corner to the southeast corner. Townships have distinctive locational identities, expressed as so many *townships* north or south of a particular baseline and so many *ranges* east or west of a particular prime meridian—downtown Chicago, for example, lies in T39N.R14E, that is, the 39th township north of the Centralia Base Line and the 14th range east of the third principal meridian.

Each section of land may be further subdivided into quarter sections (160 acres) and quarter-quarter sections (40 acres), the latter being one of the smallest standard land units sold or granted to private interests, apart from the irregular fractional sections formed by intersecting watercourses, coastlines, survey correction lines, or, in the rare cases of government townsites, townsites lots. Recipients of land in the township and range system have generally been free to select land parcels in almost any geometrical combination of subunits within the checkerboard consistent with purchase and payment requirements that have varied with federal land policy over time. Every discrete land unit within this national survey system is described by a unique geographical reference system, expressible in alphanumeric shorthand. Land descriptions are read from the smallest division to the largest (e.g., the NW1/4 of the NW1/4 of Sec. 9 of T39N.R14E). Such geometrically simple description facilitated land reconnaissance and purchase by intending pioneers and distant purchasers alike; it has greatly simplified the registration of billions of land parcels in this continental-scale nation and constitutes the basis of most land transfers and ownership today. Since 1785, almost 1.5 billion acres have been surveyed into townships and sections.

The spatial regularity of the township and range system at every geographic scale—whether viewed locally on the ground or synoptically from the air—is extraordinary. This order is especially remarkable considering the relatively crude surveying instruments available and the sometimes

severe environmental conditions under which much of the original surveying was done, most of it accomplished during the 19th century across terrain regarded as utter wilderness. In many localities, small departures from cardinal orientation of lines and from strict acreage results occurred due to errors caused by these circumstances and also by other factors, including, for example, the presence of ferrous metals in mountainous locations that threw off surveyors' compass readings. Other departures from the strict checkerboard occur when the surveyed lands border prior land grants that, if recognized by the U.S. Congress, were left intact, embedded within the U.S. surveys that wrapped around them.

The influence of the township and range system on the settlement geography and cultural development of the United States has been profound. It created the largest gridded landscape in the world, and its rigid imposition on the land, regardless of relief, drainage, soils, and other natural features bearing on sustainability, produced a sometimes awkward fit with the natural environment. Its very layout, coupled with the federal government's policies of acquisition, encouraged the wide spatial dispersion of individual farm settlements across the land rather than community-based,

group settlements focused on village life. The inherent physical isolation this built into the pattern of rural colonization had deep, enduring consequences for the development of the American social character, even after the balance of the nation's population shifted largely from rural to urban environments.

TRADE

Trade is usually defined as the exchange of goods and services among countries. That exchange is a type of spatial interaction, or movement, that has long been a fundamental component of the study of geography. The analysis of trade is often split into two basic parts. One part, largely the interest of economists, concerns the structure of trade or the selection of goods and services that a country produces for exchange with other countries. The second part concerns the pattern of trade, or the geography of the exchange of those goods and services. It is the pattern of trade that is of primary interest to geographers, who have long studied the flows between countries. In studying those flows, geographers have also considered their institutional context, including government policy, and their effects at both the national and subnational regional scales.

What Is Traded?

The spatial pattern of trade is of primary interest to geographers, but flows among countries are often viewed as the result of their relative efficiencies in production. In the 1770s, Adam Smith argued for the economic benefits of trade based on specialization of production between countries. That specialization argument was advanced further by a contemporary of Smith's, David Ricardo, in what is called the law of comparative advantage. That law is derived from an analysis of two countries in which each is able to produce the same two commodities. Even a slight difference in the relative costs of production between the two countries can be shown to be the foundation for trade between them that will result in an overall increase in production and, by implication, lower costs for producers. The law of comparative advantage is a common foundation for many arguments in favor of free (or liberal) trade and of neoliberalism in general. Working in the early to mid 20th century, economists described the sources of comparative advantage in terms of the factor endowments of places and the factor intensities of industries. According to their requirement, factors of production such as labor or capital are unevenly distributed from place to

place; some industries are labor intensive, and some are capital intensive in production. When factor intensities of production and factor endowments of places are matched, then comparative advantage arises, and trade can produce benefits. For example, one country well endowed with labor would produce labor-intensive goods to trade for capital-intensive goods produced in a country well endowed with that factor.

Comparative advantage/factor endowment theory is focused on differences in supply conditions between countries as the basis for trade, but more recently, market similarities between countries have been theorized as trade inducing as well. If consumers in different countries have similar incomes and tastes, according to this approach, then producers in those countries will find ready markets for their goods in trade because they produce goods that are attractive in each other's market in terms of their basic characteristics and also because consumers will enjoy the variety that such trade affords. Even if goods are produced for other industries, and not for consumers, the argument holds. Different countries will have producers of specialized goods that can be sold in other countries with similar industrial composition. Similarities in consumption preferences seem easily applicable to trade in services, such as those provided in professional and financial markets and in transportation. Another major component of service trade, however, is tourism, which may conform to differences in "factor" endowments such as good weather, beaches, and cultural attractions.

Geographical Patterns

Actual geographical patterns of trade are likely the inspiration of trade theory. Comparative advantage and /factor endowment theory suggests that trade will most likely occur between countries that are economically very different from each other, which was the most noticeable pattern of trade during the colonial and late imperial eras. European countries imported raw materials from their colonial possessions, which were well endowed with natural resources, or they imported other primary products such as sugar and cotton produced by large numbers of slaves or, later, by very low-cost labor. In turn, the Europeans sold

Stacked shipping containers, lighters, and cranes at a container terminal on Victoria Harbor, Hong Kong

manufactured goods in their colonial monopolies. More recently, the flows of trade between countries that are similar in their high incomes are easily observed, which is why trade theory has focused on market similarities between countries rather than on differences in production costs. In fact, trade among similarly wealthy countries is so prominent that trade is often described using a gravity model, which typically ignores production costs in its specification.

The typical gravity model is specified as $T_{ij} = f(G, I_i \dots I_j, 1/D_{ij})$, where T_{ij} is trade between two countries i and j , G is a constant defined with respect to what is being traded, I is income, and D is some cost of transporting G . Such gravity models have been used frequently to describe trade, indicating that the major factors promoting trade are the incomes of trade partners, not differences in production cost, while a factor in reducing trade is the cost of transportation. In short, the gravity model describes a pattern of trade that is most readily observed between wealthy countries

located in close proximity to each other. It also describes trade as least likely between poor countries that are distant from each other. In general, the gravity model is correct. Measured by value or volume, trade in both goods and services tends to be greatest among the world's wealthier countries, followed by trade between wealthy countries and poorer countries, while trade among low-income countries is a distant third. That general pattern has been roughly stable for a long time, but the place of individual countries changes. A notable example of changing trade is that between China and Brazil. Both have experienced significant income growth recently, and the trade between them has increased significantly as well.

Policy and Customs Unions

Trade theory assumes that trade is liberal, that is, devoid of government restrictions, and at the same time is the justification for liberal trade policies. Actual trade, however, occurs in an institutional

framework in which government-directed commercial policy plays an important role. Common instruments used by governments to inhibit imports, for example, are tariffs and quotas. *Tariffs* are taxes on imported goods that governments have used both to raise revenues and to protect domestic producers from trade competition by offsetting other countries' advantages in production costs. *Quotas* are limitations on the physical quantity of imports; only so many square meters of cloth can be imported, for example, or so many automobiles. Such a physical limitation not only raises the price of the imported good by inducing its scarcity, it also allows for domestic monopolies to form among a country's own producers. Recent multilateral trade agreements have had the general trend of reducing tariffs and quotas in the interest of promoting more trade, under a neoliberal mindset. Such agreements have also encouraged the reduction of other means of limiting imports, such as the requirement that they meet certain environmental or safety standards in their production.

While much commercial policy is focused on limiting imports, some of it is aimed at promoting exports or supporting high prices for export goods in other countries' markets. Export processing zones have been established by many countries as geographical areas in which producers enjoy special tax rates and other benefits as long as they are engaged in producing goods for export. Governments also try to manipulate exchange rates in such a way that the goods produced in their own country are relatively inexpensive in other countries, while imported goods remain highly priced. Export prices in some markets are encouraged to remain high if demand can still be sustained. The Organization of Petroleum Exporting Countries, for example, is a cartel of suppliers that uses internal production quotas to target prices in the global oil market.

More general trade agreements among several countries are referred to generically as customs unions, but those agreements can take many forms. Some countries combine into free-trade areas, in which goods and services may pass across common borders (nearly) without restriction as long as the member countries are the places of production. The North American Free Trade Agreement establishes a free-trade area that includes Canada, Mexico, and the United

States. Actual customs unions act as free-trade areas with the additional characteristic that the member countries have common trade policies, including tariff rates, toward nonmember countries. The European Union that emerged in 1993 was developed from a customs union called the European Common Market, which was completed in 1968. There are many variants of customs unions in places around the world, including Mercosur in South America and the Economic Community of West African States.

Geographical Effects of Trade

Trade policies are developed and customs unions are formed because trade has economic effects on countries that are of interest to governments. Going back to the theory of comparative advantage, there is a strong argument that trade can lead to economic growth. Most governments, however, are not usually encouraging of trade in general but rather of exports in particular. Several East Asian countries are often used as examples of export-led economic growth, including Japan, South Korea, Taiwan, and, especially, China. Policies that promoted exporting have been employed in each of those countries over time, and each of those countries has experienced very high growth rates from very low starting points in recent history. At the same time that governments usually encourage exports, however, they also tend to discourage imports. Increases in imports can often lead to problems for domestic producers of the same good or service. While the law of comparative advantage indicates benefits of trade in aggregate, it also indicates that any country should expect both winners and losers as industrial specialization among countries develops along with increased trade. Wage and profit declines or even significant loss of employment and income can occur in some industries as their country opens its doors to more imports, and governments are often petitioned by the injured parties for protection. Protection is also sought by groups before imports are allowed to increase by groups that anticipate injury.

The effects of trade can also vary geographically within countries. Some geographical effects are felt in those parts of a country in which an

industry injured by trade is concentrated, while positive effects typically arise in those parts in which more highly competitive industries are located. Policy often has geographical effects. China's economic liberalization, for example, especially targeted export production along its coast. That strategy has led to an uneven distribution of the benefits of trade, with much higher incomes on the coast than those that prevail in the interior. Many parts of a country, regardless of policy, seem to have a locational benefit with respect to trade—border regions, for example, with respect to lowering transport costs—while less accessible parts of countries are often less favored by positive trade impacts or more inclined to have a disproportionate share of the costs of trade.

TRANSNATIONAL CORPORATION

The term *transnational corporation* (TNC) is used to describe firms with overseas operations and is often used interchangeably with other terms such as *multinational corporation* or *global firm*. TNCs play a significant role in processes of globalization and are collectively a key actor in the global economy. A qualitative shift in the nature of the global economy since the 1970s has seen processes of globalization accelerate, and transnational firms are both a cause and an outcome of increased global economic integration. The unevenness of global economic activity is in part a result of the investment decisions made by the world's largest firms. Interest in TNCs—from academics, policymakers, and governments—focuses on their growth, geographies, investment decisions, and impacts on national economies.

Definition and Measurement

There are many definitions of TNCs, ranging from the simple notion of firms that have operations in more than one country to more sophisticated conceptualizations that acknowledge the complexity of firm internationalization. The most widely used definition in geography is by Dicken (2007), who defines a TNC as “a firm that has the power to coordinate and control

operations in more than one country, even if it does not own them” (p. 106). This definition offers an important qualification that transnational corporations are not simply “present” in more than one country. Their transnationality results from the nature of their presence in different markets and their organizational structure. TNCs are engaged in a wide range of different industrial sectors ranging from resource extraction to services such as banking. They share three basic characteristics:

1. Operations within and between different countries, coordinated and controlled through transnational production networks
2. The ability to use such networks to exploit global geographical differences in the distribution of resources
3. Flexibility to shift their geographical locations

Transnational firms can be measured in a variety of ways, for example, overseas revenues, number of employees, transnationality, geographical spread, overseas profitability, and many more. In 2005, the biggest company in the world (as measured by total revenues) was ExxonMobil, the world’s largest employer was Walmart, the firm with the greatest foreign assets was General Electric, and the United Nations Conference on Trade and Development ranked Canadian media firm Thomson Corporation as the most transnational and Deutsche Post as having the greatest geographical spread. The total number of TNCs is growing yearly. Between 1970 and 1998, the number of TNCs worldwide grew from 7,000 to an estimated 53,600, with some 449,000 foreign subsidiaries.

Evolution of TNCs

The geographical expansion of firms outside their home territories is not a new phenomenon. Historically, companies such as the East India Company and Hudson’s Bay Company developed extensive geographical networks to trade over large distances. However, the modern transnational firm emerged in the second half of the 19th century as part of a dramatic increase in international economic activity. Processes of

globalization accelerated after 1945, and increased internationalization and integration were enabled by two interrelated processes: first, the rapid development of technologies of time-space compression—travel was quicker, cheaper, and possible over greater distances, and developments in telecommunications facilitated transnational communication—and second, the introduction and development of flexible systems of production and organization in firms. By the 1970s, firms were increasingly investing in overseas markets and integrating production and distribution across a range of different territories.

There are two main types of international production. *Market-oriented production* sees foreign direct investment (FDI) in production facilities inside a new market. Firms are attracted to particular markets for a number of reasons, but the most common are market size (such as the large markets of the United States and China) and/or markets with particular demands for products based on national income levels (e.g., the increased demand for consumer goods in the newly emerging economies). *Supply or cost-oriented production* sees TNCs locating production at the site of supplies of particular commodities. These commodities could be raw materials (such as timber, minerals, energy resources) or labor (to exploit geographical differences in labor costs, productivity, and skill levels).

As business firms began exploiting the new global opportunities offered through technological advancement, they reorganized and restructured in response to the challenges faced by their internationalization strategies. Organizational structures are forced to change as traditional models are unable to respond effectively, or quickly, enough to the demands of operating not only in more locations but with greater links between each location. Barlett and Ghosal (1989) suggested four major ideal types of TNCs that help trace the development of a firm’s organization as it internationalizes. First is the “multinational” organizational model, in which, as a firm internationalizes, it establishes offices in new national markets. These branches are fairly autonomous, and headquarters maintain control over finance. Second is the “international” organizational

model, in which overseas operations are more integrated into the domestic corporation. Third is the “classic global” organizational model, in which the headquarters act as a centralized hub and coordinate most decision making. Overseas operations are treated as input and output points feeding the firm’s global market. Fourth is the “transnational” organizational model, in which headquarters oversee a complex integrated network, coordinating components, products, resources, people, and information. This model is an outcome of the dilemma facing TNCs in today’s turbulent, competitive global economy. Firms need the best features of each of the four types at the same time: They need to be globally efficient, flexible over a number of geographical territories, and capable of transferring knowledge across their global networks.

A key part of TNC restructuring has been a shift in the coordination of supply chain inputs to gain cost and time efficiencies. Firms continue to review the degree to which certain functions are retained within the firm or outsourced to other companies. Recent decades have seen a substantial increase in externalized supply relationships, with firms outsourcing functions such as information technology, back offices, logistics, human resource management, and production. For example, Dell, the world’s second largest maker of personal computers, outsources customer service functions to India and Latin America and manufacturing to contractors predominately based in Asia. Such examples of outsourcing often occur over large geographical distances. However, the adoption of “just-in-time” production techniques and technologies has encouraged the colocation of firms and their suppliers as closer geographical proximity aids flexibility and responsiveness to demand. In the automotive sector, for example, large production plants include the original equipment manufacturer (e.g., General Motors), a large number of supplier firms producing components (e.g., car seats, windshield wipers), and even branch offices supplying temporary labor to work on the production line (e.g., Adecco). Therefore, as a result of the realignment of supply relationships, the scale at which firms coordinate their production chains has shifted to the regional or global scale. However, the resulting geographical “footprint”

of the firm (i.e., where it actually conducts production, final assembly, and delivery to customers) is highly dependent on the management and strategies of the firm and, crucially, on the sector in which it operates.

Factors Influencing the Geography of TNCs

While TNCs share many characteristics, there is great variety in the shape and size of TNCs, both within and across different industry sectors. No two firms are the same, and even closely competing firms make (sometimes radically) different strategic and locational decisions. TNCs should be understood as inherently complex, constantly evolving, and unique. The sector in which the firm operates, the national context, and the ownership structure are among the key factors that shape the TNC.

Sector

First, the sector of which the firm is part plays a decisive role in determining its geography. For example, British Petroleum’s production sites are dictated by the source of raw materials and extraction technologies. Many of these sites are located in lower-income nations such as Kazakhstan, Botswana, and Bolivia. In comparison, in labor-intensive industries such as garment manufacturing or call-center operations, firms seek sources of cost-effective labor. The majority of the world’s garment manufacturers have production sites in Asian economies, including China and Cambodia.

National Context

Second, the “nationality” of the firm shapes and influences the geographical contexts in which they are situated, and this is especially true of their country of origin. The national context in which a TNC is headquartered influences the firm culture, the nature of supplier relationships, and the regulation of finances. In addition, the size of a firm’s home market determines the drive to internationalize as firms in large markets such as the United States may expand overseas later than a firm based in Belgium.

Ownership Structure

Third, the ownership structure of a TNC can affect its management and corporate strategies, particularly internationalization and sourcing decisions. The majority of TNCs answer to shareholders, which may result in short-term demands for return on investments. However, some TNCs are privately or government owned, which can have a significant impact on competitive decision making, imposing limitations on accessing finance for expansion and, in the case of government-owned enterprises, regulatory restrictions on operations.

Impacts of TNCs

Much rhetoric surrounding TNCs credits the firms with immense powers and omnipotence. TNCs are viewed by some, particularly in the popular media, as renegade entities scouring the globe for investment and exploitation opportunities to generate vast profits. While such views are often overstated, they reveal two key debates surrounding TNCs: their “placelessness” and the impacts of their location decisions. First, the suggestion that TNCs operate completely freely across the global economy is refuted by geographers. In many ways, the importance of place is confirmed by the location decisions of TNCs—the global economy is not an even playing field. Huge differences in the distribution of raw materials, labor, and transport infrastructure result in a complex, shifting, and uneven mosaic of local and national economic spaces, and it is these disparities that TNCs seek to exploit through their internationalization strategies. While nation-states are attracted by FDI from TNCs, the scale and extent of TNC activity does pose some problems for national economies. For some, TNCs have surpassed nation-states as the key actors in the global economy. This status raises concerns for nations regarding their ability to shape and guide their economies and compete internationally. However, the relationship between TNCs and national governments is not as one-sided as it may seem at first glance. The nation-state creates the geographical contexts in which TNCs operate. With the exception of some supranational regulation (e.g., through the European Union or

trade agreements), the conditions in which TNCs are embedded in any context are regulated by the national government. This covers aspects of business such as labor regulation (wages, terms, and conditions) and finances (taxation, investment incentives).

Second, the impacts of TNCs in host economies are contested. Some suggest that TNC investment in lower income countries keeps economies relatively backward and dependent on advanced capitalist nations for investment, jobs, and technology, while others argue that FDI by TNCs is an instrument for dispersing the production of goods and services to those locations where they can be most efficiently produced. Many geographers are situated in between these dichotomous viewpoints and suggest that FDI has both benefits and costs to host economies. Benefits can accrue through a number of mechanisms. For many countries, FDI by TNCs is an important source of capital and employment. The TNC may use local suppliers, thereby increasing benefits as employment increases and knowledge is transferred from the TNC to the local firms. The costs of FDI include the financial incentives offered to the TNC (such as tax incentives and/or the provision of infrastructure), the degree of revenues generated as the foreign operation remits earnings and profits back to its parent company, and the quality of jobs created. A key concern is whether the host economy is able to capitalize on the benefits of FDI to “upgrade” local industry, skills, and work standards and connect further into the global economy. If the costs outweigh the benefits, the host economy may find itself as a temporary low-cost location for the TNC in which low-skilled labor is provided without tangible benefits accruing. Not all FDI impacts are related to the economy, as TNCs are also important transmitters of social, cultural, and political change, particularly in developing countries. Again, these changes can be both positive and negative and vary depending on the TNC and the host economy in which it is located.

TRANSNATIONALISM

Transnationalism denotes processes and practices through which contemporary international migrants forge and maintain ties across national borders to their countries and places of origin. The acceleration of economic globalization has enabled these migrants to create new transnational social and cultural spaces that span multiple polities and societies. Migrants create these new social spaces by, among others, sending money home to family members in the form of remittances; they influence the political lives and well-being of their home places through hometown associations, contribute to economic development projects in their countries of origin, or participate in religious and cultural organizations that span national borders. While these new social spaces are similarly facilitated by innovations in transportation and communication technologies, migrants' "transnationalism from below" differs from globalization from above in that it is individual migrants' and groups' social practices rather than the economic power of transnational corporations that create new ties between places.

The terms *transnational migrant* or *migrant transnationalism* were made popular by Nina Glick Schiller, Linda Basch, and Christina Blanc-Szanton, whose observation of migrants' continued engagement across borders through multiple

practices led them to suggest that contemporary migrants differ from previous waves of immigrants in that they no longer need to give up ties to their home places and face less pressure to assimilate to the host nation. Glick Schiller, Basch, and Blanc-Szanton initially suggested abandoning the term *immigrant* in favor of *transmigrant* to reflect that migrants live their lives across borders and in multiple nation-states. Emphasizing migrants' resistance to changing political and economic conditions in a globalized economy, they proposed rethinking conceptions of ethnicity, race, and nation. Such assumptions were echoed in postcolonial and cultural studies that suggested that transnationalism, aided by new mass media such as satellite television, was fostering new cultural identities that stretched beyond national and local contexts and undermined nation-state and nationalist projects.

This initial enthusiasm seemed to overshoot the conceptual and explanatory power of transnationalism and prompted criticism from scholarship in the social sciences that has since sought to refine several aspects of the initial conception proposed by Glick Schiller and colleagues. Some of these extensions and refinements constitute attempts at creating types and taxonomies of transnationalism aimed at better defining what does and does not constitute transnational processes and practices. These taxonomies distinguish economic, sociocultural, and political practices with low and high levels of institutionalization. In a taxonomy proposed by Portes, Guarnizo, and Landolt, hometown associations are considered political transnational practices with a low level of institutionalization, whereas cultural events organized by foreign embassies are considered highly institutionalized sociocultural practices. The frequency and regularity of transnational practices in question receive additional consideration in such typologies. There is debate about the usefulness of such typologies, and more recent work has instead sought to examine migrant transnationalism in relation to multiple axes of difference.

The extent and intensity of transnational practices vary according to the socioeconomic positionality of migrants and the conditions in sending and receiving societies that limit or enable transnational mobility. Among the factors facilitating and constraining transnational mobility are gender,

class, and migration status. So-called hypermobile migrants, or “astronauts,” travel with ease across borders, for example, the Hong Kong Chinese business executives who bought property on the Pacific Coast of Canada. These “transnational elites” are able to take advantage of the globalizing economy by maintaining investments and economic interests in Hong Kong while raising their families in Vancouver. In contrast, poorer migrants’ transnational practices often remain limited to sending remittances to family members or making phone calls, especially if these migrants’ mobility is constrained due to their insecure status as refugees and asylum seekers. Undocumented migrants face even more restrictions because they lack the proper papers that would allow them to travel across borders with ease.

Rather than juxtaposing the home and host countries, geographic research instead shows how migrants forge complementary local, national, and transnational ties. This research questions claims that assimilation is no longer necessary for contemporary migrants. Geographers have examined the complex spatialities of migrant transnationalism as they emphasize how identities are constructed in relation to both home and host places, as migrants negotiate the contexts of both. The analysis of the daily practices of Salvadoran migrants under Temporary Protected Status in the United States demonstrates the difficulty of migrants’ struggles to create and maintain transnational (social) spaces in efforts to connect to their places of origin while coping with status insecurity in the United States. This research grounds migrants’ transnational ties in the lived experiences of their everyday lives and shows that transnational spaces are created, in part, through place-making practices and the creation of local ties.

Migrant transnationalism presents new challenges and opportunities for sending and receiving states. Restrictions imposed on refugees and other migrants demonstrate that transnational mobility is facilitated, regulated, and limited by sending and receiving states. Because migrant remittances form an important revenue source for them, sending states have increasingly been creating provisions for extraterritorial voting, dual nationality, or dual citizenship to bind their citizens abroad to the state of origin. These legal changes also affect receiving states, which

increasingly allow dual citizenship. Such changes in citizenship law prompted by the transnational realities of contemporary migrants are frequently accompanied by fierce public and political debates. The attacks of September 11, 2001, in particular, have prompted debate about migrants’ transnational practices, citing security and border control issues while highlighting the potential for terrorism among migrant populations. This is particularly salient for Muslim migrants, whose religious faith is portrayed as undermining liberal democratic values. More generally, the political attachments, loyalties, and activism of contemporary migrant populations have moved to the center of public debate and of researchers’ attention. As numerous migrants remain citizens of their country of origin and engage multiple polities across national borders, hosting states and societies question their loyalty to the receiving polity. Migrants’ collective political identities, activism, and practices of citizenship are thus part of the study of transnationalism as they challenge and change a state-centered approach to politics.

TRANSPORTATION GEOGRAPHY

Transportation geography is the subfield that deals with the movement of people and goods across space, as well as the social and material infrastructures that enable or constrain those movements. More than most subfields of geography, transportation geography has strong connections with outside disciplines, including economics, engineering, planning, and landscape architecture. On the one hand, these linkages have led to a greater engagement with policy making than in most areas of geography. On the other hand, the subfield has also come under criticism for its somewhat narrow focus and isolation within geography. That said, transportation geography has made significant contributions to the discipline in demonstrating the importance of gender, the integration of economic and environmental concerns, and the need to engage with policymakers, among other areas. Particularly in the current era of globalization, connections between distant peoples and places are of growing importance, and transportation geography is key to understanding how those connections happen (or fail to happen). In terms of researchers, practitioners, and productivity, this is a subfield that is on a positive growth trajectory.

This entry is organized according to a series of categories into which most transportation geography research can be sorted. However,

many of these categories have begun to merge as the transportation industry and the study of it have become more integrated across modes and places. Significant opportunity exists to draw from emerging areas within geography and related disciplines to further strengthen this subfield and for other geographers to incorporate insights from the study of transportation nodes and networks.

Passengers and Freight

At its most basic level, transportation geography is concerned with the movement of people and goods. With respect to the former, this includes the travel choices and constraints of individuals over long and short distances: how mode choice, trip length, and destination are constrained or enabled by the available networks. With respect to the latter, the movement of people and goods includes the choice of mode and route with an eye toward minimizing cost. With respect to both, it includes the broader social and economic contexts, including cost as a decision factor, as well as the impacts on land use.

The main focus of transportation geography is on the movement of people, ranging across modes and scales. Much early work focused on the policy implications of suburbanizing metropolises, later evolving into a significant literature on excess commuting that tried to explain the long average distances between home and work. Long-distance and international travel have also been key areas of study, from tourism and migration to more recent work that uses flights or passengers as a proxy for connections between world cities in a global network. New cultural and social approaches explore the consumption of transportation in terms of the symbolic meanings of vehicles and of motion itself.

Research on the geography of freight transportation has evolved along with the industry. The early focus was on freight rates, linear programming, and the “transportation problem” from economics, in keeping with the regulated nature of freight transportation in the mid 20th century. Connections between freight transportation and land use focused on cities as historical break-of-bulk points, with general conceptual models describing evolving relations between colonial

cities and their home ports, the relations among colonial cities, and the relations between ports and their surrounding cities. As the industry deregulated and became more entwined with globalizing economic activity, the research focus shifted to containerization, logistics, and the ensuing changes in all transport modes. More recent approaches include global commodity chains, logistics and supply chain management, and the new landscapes of distribution centers and intermodal terminals.

Accessibility/Mobility

One of the most basic distinctions drawn within transportation geography is between the concepts of accessibility and mobility. Generally speaking, accessibility refers to the presence and extent of infrastructure networks, while mobility refers to the movements of people and goods along those networks. Both have important implications for social equity and economic impact.

von Thünen's classic model of economic activity as concentric rings around the city is based on accessibility, measured as proximity to the city center. Accessibility is also at the core of models of the evolution of North American urban form at the regional and metropolitan scales, respectively, as the predominant modes of long-distance and commuting travel changed over time. More recent models of urban form take into account the polycentric form of the modern North American city and the need to access multiple locations for work, shopping, and so on. Accessibility can also be measured through network analysis, as has been done for airports to show changes across time due to deregulation, airline mergers, and political change. It can also be studied in terms of the effects it has on land use. For example, the impact on urban land prices of introducing fixed mass transit (such as a light rail line) is a subject of much debate.

A tugboat pulls a freight ship through the Corinth Canal, Greece.

Source: David H. Seymour/iStockphoto.

However, the simple fact that infrastructure exists does not mean that all people have access to it. The classic example is the limited-access highway, with the evacuation of New Orleans after Hurricane Katrina as a more recent demonstration. The mobility aspect of transportation geography focuses on how easily people can get to and use transportation infrastructure: proximity to a highway or bus stop, vehicle ownership, or wheelchair access, for example. Of particular interest is the “spatial mismatch” problem, where locations with a surplus of jobs (often in the suburbs) may not be easily accessible to the unemployed (often in central-city neighborhoods).

because of poor transit connections and low vehicle ownership.

The concept of “mobility” is not to be confused with the recent work coming out of sociology and related disciplines on “mobilities.” The most prominent work in this regard has been the concept of automobility, describing how modern society is inextricably intertwined with the production and consumption of automobiles and the mobility they provide (and followed more recently by aeromobility, velomobility, and other modes). Much of this work focuses on the need to examine everyday spaces and journeys to understand how people, places, and mobility construct each other. Geographers are just beginning to incorporate this theoretical approach into research on the construction of space, place, and policy.

Aggregate/Disaggregate Approaches

Planners and geographers alike generally approach transportation systems from one of two ways: (1) in the aggregate, based on territories such as census tracts or counties, (2) or in the disaggregate, focused on individuals or households. In particular, planners tend to take the former approach, looking at flows of commuters or travelers at a large scale. However, while a disaggregate approach may be more time-consuming in terms of data collection and analysis, it offers a better understanding of the opportunities and constraints individual travelers experience, as well as the reasons behind their travel decisions.

Aggregate flows are generally broken down into five categories of study: trip purpose, trip time, modal split, trip length, and spatial patterns. Within the United States, trip purpose has experienced a major shift in recent decades, with the majority of trips now being made for non-work purposes and with a concomitant shift in spatial patterns. Trip time and length have increased on average, with both contributing to the worldwide increase in vehicle miles traveled (VMT) at a much faster rate than population growth. Modal split continues to be heavily biased toward the automobile in developed countries, and increasingly in developing countries as well. The spatial pattern of trips can be used to characterize different urban areas, from the strong bidirectional flow of traditional commuters that

enables a mass transit system such as New York City’s to capture a majority of commuting trips to a multinodal space such as Los Angeles, with automobile congestion in all directions.

The disaggregate approach to transportation is exemplified by Hanson’s work on the different transportation experiences of men and women, which led not only transportation geography but the discipline as a whole to consider the role that gender plays in the production of space. This work has since been expanded to include differences based on class, race, age, disability, and other markers of social differentiation. Travel diaries and interviews are the most common methods for disaggregate analysis. More recently, Kwan and Miller have revived time-space maps with the use of geographic information systems to visually represent the daily travels of individuals throughout a city or region. While data collection is often a limitation of the disaggregate approach, it involves fewer simplifying assumptions than aggregated studies and can lead to richer results.

Public/Private Dimensions

Public versus private financing of transportation is one of the major distinctions among modes and places. A significant contribution of transportation geography has been close examination of the impacts of deregulation and privatization since the late 20th century. For example, Goetz’s study of U.S. airline deregulation clearly demonstrates the importance of a geographical approach, as the average decrease in airfares following deregulation is more properly described as a price savings in places benefiting from competition as against a price increase in cities where one airline holds a monopoly or near monopoly. Similarly, the ongoing privatization of airlines and airports in Europe and Asia is changing air travel patterns in those regions, most notably by increasing accessibility for the average traveler. The deregulation and privatization of railroads, trucking, and buses, however, have received less attention.

On the public side, a considerable amount of work has examined the economic impact of public investment in transit and other transportation infrastructure. As North American cities have inaugurated or revived light rail in the past few decades, geographers have studied the impact on

land values, ridership, and residential and other types of development. The results demonstrate weak or strong spatial connections between public investment in transportation and economic and social outcomes, depending on the scale of analysis. This follows a long tradition of examining the impact of public financing of highway systems in both rural and urban locations. The role of investment in transportation infrastructure in promoting economic development is the central concern of transportation geography in the context of developing countries.

In recent years, transportation funding worldwide has shifted to a model of public-private partnerships and joint ventures. Transportation geographers have explored the broader impacts of projects such as the Channel Tunnel in terms of the economic development implications at multiple scales for the cities and regions along the route. They are also beginning to study the spatial impacts of mechanisms such as congestion pricing on metropolitan equity and traffic congestion.

Economy, Environment, and Sustainability

Because of transportation geography's origins within economic geography, transportation geographers have long had an interest in the connections between mobility and economic development. This connection has been explored, for example, in terms of the timing of development relative to highway improvements in both urban and rural areas, teasing apart the chicken-and-egg question to show that the type and location of development matters in answering the question. The connection between transportation and land use is also relevant here, with geographers modeling the interactions between multiple transportation users and land uses, from the neighborhood scale to the national. The economic impact of terminals (including ports, airports, and intermodal facilities) has also been studied, including the broader regional and national impacts.

On the other hand, transportation can have serious environmental impacts, and geographers have contributed by analyzing the impacts on both human and biosphere health in terms of waste generation and pollution, resource use, and the physical presence of transportation infrastructure. The widespread impacts of transportation

are clear, from individuals suffering from asthma to the worldwide effects of global climate change, to which transportation contributes as the source of one fifth to one third of global carbon dioxide emissions. Road building in developing areas of the Amazon has been shown to reduce biodiversity and increase deforestation, while runoff from roads has negative effects on ecosystems all over the world. On a different note, recent U.S. research has shown a possible connection between living in a low-density suburb and being overweight among both children and adults. This connection between the built environment and human health is an important topic of current debate within both geography and planning.

These two areas of economy and environment are slowly being brought together through the concept of sustainable transportation. Incorporating the larger definition of sustainability as having economic, environmental, and social components (in roughly that order), sustainable transportation is one of the fastest-growing areas of study within transportation geography. International collaboration on ways to reduce vehicle emissions and energy consumption (including alternative fuels), to alter land use patterns in order to reduce vehicle miles traveled, and to move people rather than cars is currently one of the most exciting frontiers of this subfield. As automobile ownership and per capita vehicle miles traveled continue to rise around the world, this is also one of the most important areas of study.

Modes and Intermodalism

Traditionally, transportation geographers have tended to focus on one mode at a time, whether road, rail, water, air, or (occasionally) pipelines. Because of the different economic, social, and financial contexts of each of these modes, work on one mode has tended to remain largely separate from others. However, recent trends within the freight industry in policy and planning indicate that multiple modes and intermodalism are becoming more important topics of study.

While the transportation system itself remains dominated by the automobile, transportation geography is more equivocal. Significant work exists on the causes and consequences of automobile use for commuting and recreation, particularly

within the history of suburbanization. As the consequences of exclusive reliance on the private auto become more and more clear, researchers have tried to identify alternatives, explain why individuals make the choices they do, and demonstrate how current policies promote unsustainable outcomes. For example, while telecommuting and e-commerce were expected to reduce the need for travel, studies have shown that telecommuters do not necessarily make fewer trips and goods still need to be delivered to the consumer whether or not they pass through a store first.

Although research on rail in North America has declined in tandem with the decreasing use of this mode in the 20th century, the recent increase in freight traffic may signal an upsurge in academic work as well. Passenger rail has been well studied in Europe, particularly as competition for air travel on short-distance trips. Rail in the form of public transit is also well studied, particularly with regard to the land use implications of new and expanded metropolitan networks both historically and in the present (such as property values, job attraction, and residential density).

Maritime studies have generally focused on changes in the shipping industry as a result of containerization. An early period of centralization among North American port cities is being supplanted by some decentralization in response to port congestion. While books in the popular press have emphasized the importance of containerization to globalization, transportation geographers have focused on shipping lines and terminals and only recently looked at inland ports and connections to industrialization in places such as the Pearl River delta. As inland waterways become more important in Europe and elsewhere, attention is turning to that mode as well.

Similarly, studies of air transportation have tended to focus on the vehicles and terminals themselves rather than the broader environmental, social, and economic impacts of air transportation. Nevertheless, there have been significant contributions in terms of the impact of deregulation and low-cost carriers on air transportation networks around the world. Additionally, recent work has studied the diffusion of SARS (severe acute respiratory syndrome) across airline networks and the consequent health implications. The growing mobilities literature has placed

special emphasis on aeromobility in defining and constructing the modern era. However, of the four main modes, air transportation's connections to land use remain the least understood.

Finally, as the freight industry has become intermodal, thanks to containers that can travel by land, sea, or air, geographers' attention has turned toward intermodal facilities as well. Metropolitan areas face challenges in terms of retrofitting or adding infrastructure to accommodate the growth in freight traffic and its intermodal requirements, and geographers are well positioned to explain the importance of context in shaping logistics networks. Research is also examining the rail-airport connections that are growing across Europe, where intermodalism is relevant to passenger travel as well.

Conclusion

In keeping with general trends in the social sciences, geography has become more oriented toward networks and flows rather than places and territories. Transportation geography has always had this orientation, based on its subjects of study. The incorporation of places *with* networks, territories *with* flows, has long been a strength of this subfield, positioning it well within the discipline as a whole. On the other hand, while it was at the forefront of the quantitative revolution, transportation geography has been criticized in recent years for not having moved beyond that point in terms of methodology and subject matter. While it is true that transportation geography remains one of the most quantitative areas of geography, it has used that to its advantage in terms of close connections with related disciplines and with policymakers. Nevertheless, there is considerable room as well as opportunity for transportation geographers to incorporate broader processes and discourses, such as globalization, neoliberalization, and the cultural turn of its parent, economic geography. Because transportation enables most economic activity and social activity, it is of vital importance for geographers and others to be aware of and incorporate the work being done in this subfield. The processes of globalization have only strengthened the importance of transportation geography, and the ever-increasing movement of people and goods,

combined with a growing concern over energy and environmental costs, ensure that it will continue to be key for many years to come.

TRAP STREETS

Trap streets is a term used to refer to the cartographic convention whereby mapmakers deliberately insert fake places (such as streets and street names) into their maps so as to later be able to demonstrate plagiarism by other cartographers.

For well over a century, the U.S. court system has dealt with copyright infringement lawsuits brought when a cartographer or publishing company believes that their maps have been directly copied by a competitor. Because maps are widely assumed to be depictions of reality, it is difficult to determine whether mapmakers have compiled original research or copied directly from another cartographer in creating their maps (what the cartographer Mark Monmonier has referred to as “editing the competition”). Hence, map companies will at times add streets, street names, towns, or other features, often in out-of-the-way places, so as to later detect copying by competitors. Such deliberate errors are not confined to cartographers. Similar copyright traps have been found in dictionaries and encyclopedias as ways to detect later plagiarism.

While map companies are hesitant to point out their trap streets, such “errors” have been reported in the media in both the United States and the United Kingdom. A detailed discussion of the use of trap streets is found in a 1997 U.S. District Court decision, *Alexandria Drafting Co. v. Amsterdam*, in which Alexandria Drafting Company sued Franklin Maps for copyright infringement alleging that Franklin plagiarized Alexandria Drafting Company’s maps in Franklin Maps’ Philadelphia-area road atlases. One way that lawyers for Alexandria Drafting Company demonstrated this plagiarism was that numerous trap streets that Alexandria Drafting Company had earlier inserted into their maps subsequently appeared in Franklin’s maps. However, the use of trap streets to legally demonstrate copyright infringement was called into question in the court’s ruling in this case, which found that “false facts,” such as trap streets, are not copyrightable elements.

TRAVEL WRITING, GEOGRAPHY AND

Travel writing, by definition, is geographic. It narrates the experiences of observing places and moving through space and links travel with representation. A translation of what is seen into what is read, travel writing is of interest to geographers for its description and representation of different parts of the world. This entry discusses what constitutes travel writing, how human geographers have studied it, and what role travel writing has played in both the history of geography and the historical geographies of colonialism and imperialism. Although travel itself—whether long or short distance, temporary or permanent—is a nearly universal human experience, studies of travel writing have focused primarily on 18th- and 19th-century European and North American travelers, leaving much room for future work.

As a genre, travel writing ranges from books and serialized accounts published by well-known authors to unpublished diaries and journals kept by ordinary travelers, from texts by explorers and scientists traveling under the auspices of governments and crowns to letters by men and women traveling for pleasure. Over time, travel writing's meaning has changed. In the early 16th century, travel writings were considered forms of art and education, while in the late 17th century, they were central to the production of scientific knowledge about the “New World.” By the late 18th century, being well versed in travel writing was a sign of good taste among the European public. Across these shifts, travel writing's popularity grew, and by the 19th century, travel narratives were bestsellers.

As transportation technologies reduced the costs and difficulties of travel throughout the 18th and 19th centuries, travel writers tried to distance their work from the growing number of tourism publications. Pointing to tourism's supposed crassness, travel writers went to great lengths to show their commitment to uncovering the “authentic” character of the sites they visited and to demonstrate the value of their own first-hand experience of places. In doing so, however, travel writers did not simply “uncover” the places discussed but, instead, actively constituted them, often through comparison with familiar landscapes. In comparing, for example, the American

West with an English landscape, British travelers textually produced the new through images of the old, even as they faced the challenge of ensuring that the unfamiliar, whether Egypt or the Amazon, remained different enough to maintain travel's exotic allure.

Within human geography, travel writings have been used in various ways. In some cases, they have been treated as valuable firsthand accounts of places, such as colonial South America, or events, such as the U.S. Civil War. In other instances, travel writings have been analyzed as literary texts; and geographers have interrogated the discursive and intertextual strategies through which travelers both represented places and peoples and were in dialogue with genres from scientific and military writings to novels and political texts. More recently, geographers have used travel writings to examine how travel writers' own senses of self were differently affected by the acts of traveling and writing.

Across these approaches, geographers have studied travel writing most intensely in two areas. First, travel writing has played an important role in the history of geography as both a formal academic discipline and a broader interest in the human and physical world. Through geography's role in European colonial expansion and the impulse to map colonial territories, travel accounts of European explorers and geographers helped bring "science" and the New World to a reading public. Narratives by travelers such as Alexander von Humboldt provided detailed geographic information about the physical, social, and cultural features of colonized holdings and peoples, helping translate unfamiliar lands into territories ripe for commercial exploitation and settlement and bringing rich descriptions of these "new" places to eager readers.

In their writings, European and North American travelers often discursively erased humans from colonial landscapes, presenting lands across Africa, South America, and elsewhere as "empty" spaces awaiting European investment and definition. Such descriptions, it is important to note, frequently had material consequences, as their representations of colonial lands as latent resources fed into and justified subsequent European exploitation of these sites. Through their depictions of "native" peoples, colonial travel

Title page from the first edition of *Pictures From Italy*, a travelog by Charles Dickens, 1846

Source: Public domain.

narratives also illustrated what Mary Louise Pratt calls "contact zones," where groups and cultures met and interacted. In many cases, these interactions were deeply asymmetrical, and travel writers not only relied on native knowledge to maneuver and understand the places they observed but also were complicit with an "othering" that rendered colonial subjects both different from and inferior to European subjects.

Travel writings have also been central to geographic studies of colonialism and imperialism, particularly vis-à-vis gender. Through studies of

travel narratives by European white women in various colonial settings, feminist historical geographers have shown how gendered analyses of travel writings blur the lines between imperial, public spaces and domestic, private spaces. As they demonstrate, the inclusion of women travelers often calls into question monolithic narratives or understandings of colonialism and highlights the complexity of interactions among European and native women and men.

As this last example shows, the specifics of the social, economic, and political relations of colonialism and imperialism can be most effectively seen when travel writings by men and women, by known and obscure writers, are analyzed alongside one another. This comparative approach enriches understandings not only of the geographies and practices of colonialism but also of the transformative nature of travel itself. In the process, it offers an exciting model for subsequent work on travel writings from other historical and geographic contexts.

TREE FARMING

Tree farming, or plantation forestry, is a system of cultivated forests established by planting or seeding in the process of afforestation (converting bare or fallow land into forests) and reforestation (planting once forested land with trees or other woody plants). Tree farms are established for several reasons, for example, to produce wood biomass, especially where natural timber stands are depleted; to meet the demand for high-quality species (e.g., mahogany, cedar); to develop export markets; to conserve or restore soil and water; to protect biodiversity; and to supply potential markets for carbon sequestration. While tree farms provide numerous benefits, critics note a number of ecological and socioeconomic defects; these are summarized below.

While tree farms existed throughout the world for centuries, their incidence increased dramatically in the mid 20th century. This is largely due to the expansion of commercial timber harvesting, the growing strategic importance of the pulp and paper industry, and the depletion of merchantable natural timber stands. Tree farms are relatively inexpensive to implement and maintain, produce cash crops in greater volumes and shorter periods of time than natural forests, require little infrastructural investment, and can provide jobs in underdeveloped regions. Tree farms are intensively managed, which simplifies production and reduces silviculture and harvesting costs as well as loss of time and resources due to inclement natural phenomena. According to Roger Clapp, the shift from natural to plantation-based systems of forestry is conceptually equivalent to the agricultural revolution. Most large-scale tree farms rely on species that grow rapidly and are resistant to drought. The most common are pine, which mature in between 15 and 30 yrs. (years), and eucalyptus, which mature in as few as 7 yrs. (see photo). Acacia is also commercially grown in southeast Asia.

The inception of large-scale plantation forests occurred in the 1960s, primarily on easily accessible fallow agricultural lands in Spain, Portugal, the southeastern United States, and the Canadian province of Ontario's St. Lawrence Valley. The Weyerhaeuser Corporation also

Casuarinas growing in dunes, Zululand, South Africa. Casuarinas are planted in coastal sand dunes for the stability they provide to the ground and for their timber.

Source: © Anthony Bannister; Gallo Images/Corbis.

played a leading role in developing successful tree farms in the northwestern United States during this era. Brazil and Chile developed large-scale plantations in the 1980s that demonstrated the economic viability of commercial tree farming. Many of South America's first large-scale tree farms were established by Japanese pulp and paper firms in response to elevated North American fiber prices and the depletion of timber stocks in and the ensuing ban on log exports from southeast Asian countries. More recently, Indonesia, Malaysia, Thailand, China, India, Russia, South Africa, Australia, and New Zealand have developed large-scale plantations. According to a recent report by the Food and Agriculture Organization of the United Nations, commercial tree farms account for roughly one half of the global total while nonindustrial plantations and unspecified plantations each account for approximately one quarter of the global total. Four countries

house more than 60% of the world's tree farms: China, India, Russia, and the United States.

Commercial tree farms can alleviate pressures on natural timber stocks and reconcile the interests of environmental advocacy groups and proponents of timber-based economic development. In fact, some major timber-producing countries or regions—most notably New Zealand and the southeastern United States—derive the majority of their commercial wood fiber from tree farms, while natural forests are set aside for conservation or preservation. The spatial consolidation of timber supplies through tree farming also reduces the financial and environmental burden of transportation, which has historically been a major impediment to profitability, rationalized production, and ecological sustainability in forest-based industries. Additionally, the environmental benefits gained through tree farming are often used as a justification to access public funding for such endeavors.

Recent Debates and Controversies

Tree farms are a valuable ecological and socioeconomic component of the world's forest resources. However, recent debates and controversies highlight the shortcomings of commercial plantation forests. These shortcomings are classified as either ecological defects or socioeconomic defects, but there is often notable overlap.

The absence of multilayered canopies, the depleted water tables, the inability to protect soils, the lack of habitat for wildlife and livestock, and microclimates altered by nonnative tree species are some of the most pressing ecological defects associated with tree farming. The lack of biodiversity on tree farms also draws criticism. Because the primary objective of most tree farms is to maximize the output of timber, monoculture crops are common. Critics, however, are skeptical that such crops are sustainable in the long run and claim that the aforementioned ecological defects are the result of monoculture plantations. Additionally, monoculture plantations are disproportionately susceptible to damage by invasive or parasitic insects and flora. Many point to small-scale and nonindustrial tree farms as the best means of balancing the need for long-term ecological sustainability with the need for efficient and profitable timber production.

The socioeconomic defects of commercial tree farming are most prevalent in underdeveloped nations or regions, particularly southeast Asia and South America. Three predominant defects exist. First, commercial tree farms rarely provide high economic multipliers to local or regional economies. This is especially the case where work systems are highly mechanized and capital intensive or where production is export oriented and devoid of value-adding processing facilities such as pulp or lumber mills. Second, profits are often distributed unevenly and fall into the hands of multinational firms, corrupt governments, or military juntas. Third, the conversion of land into plantations displaces peasants and indigenous cultivators from common lands that supply pasture and fuel.

TREWARTHA, GLENN (1896–1984)

Born in southwestern Wisconsin in 1896, Glenn Trewartha was an influential 20th-century American geographer. Trewartha's academic career was impressive in both its length and scope. His publication career covers seven decades, from his first publication in 1923 to his last in 1982 (just 2 yrs. [years] before his death in 1984). Most impressively, Trewartha was a recognized leader in three distinct areas of geography: (1) weather and climate, (2) the geography of Japan, and (3) population geography.

Trewartha was hired as an instructor at the University of Wisconsin, Madison, in 1922, and received his PhD there in 1925. After receiving his doctorate, Trewartha was promoted to assistant professor at Wisconsin in 1926 (and later to associate professor and professor). He spent the next 40 yrs. at Madison before retiring in 1965 as the Finch Research Chair in Geography.

First and foremost, Trewartha was a leading expert on weather and climate. He published the very influential textbook *An Introduction to Weather and Climate* in 1937. The book went through five editions over the next 40 yrs., the

last edition being published in 1980. Trewartha is best known for his introduction of and modifications to the Koppen climate classification system. Also, Trewartha is credited with coining the term *greenhouse effect* in 1937.

In addition to his work on climate, Trewartha was also a leading American scholar on Japan. One of the first American geographers to specialize in the regional geography of Japan, Trewartha published his first book on the country in 1934, with subsequent editions published in 1945 and 1965. As a leading American scholar on Japan during World War II, Trewartha served as a consultant to the U.S. government during the war and afterward during the Allied occupation government's reconstruction efforts.

Trewartha is also remembered as the founder of the subdiscipline of population geography. As president of the Association of American Geographers, Trewartha used his 1953 presidential address to advocate for population geography as a distinct and prominent subdiscipline. He believed that population geography had long been ignored by geographers and argued that the study of population should be central to the discipline. He proposed that geography had three main elements: (1) the "physical earth," (2) the "cultural earth," and (3) population. Trewartha saw the study of population as a central organizing principle of geography and as the key linkage between the human and physical sides of the discipline.

TRIANGULATED IRREGULAR NETWORK (TIN) DATA MODEL

The Triangulated Irregular Network (TIN) is a data model that describes surfaces, especially terrain. It has been developed as an alternative to the two other data models for surfaces, the Regular (Rectangular) Grid and the Contour Model. The summary term is *digital terrain model* (DTM).

The philosophy that underlies TIN is that triangles are a good approximation of terrain that is less than smooth (i.e., has breaks such as ridges). TIN needs a fraction of the units of regular grids and is computationally faster than contour modeling.

A triangle has three components: (1) one area, (2) three edges, and (3) three vertices. It shares each edge with one other triangle and each vertex (node) with an average of five other triangles. This sharing allows the linkage of the triangles into a network. The resulting relationships are usually identified under the term *topology*.

All structures have topology. For the regular grid, topology is implicit; that is, each vertex in the network is given by its numbered location, the northwest corner usually being the position 0,0. The neighbors of vertex (i, j) are $(i \pm 1, j \pm 1)$. For the contour structure, contours often have with them stored the labels of the contours above and below (the "contour tree"). This we could call a "partially explicit" topology.

The implementation of the TIN model into a data structure can happen in different ways.

- The first structure stores in one array the triangles together with their edges and, in a second array, the edges with their limiting vertices. A third array would have the vertices

with their coordinates. All topological relations are stored explicitly.

- The second structure is based on the edge as the main carrier. With each edge are stored the labels of the two endpoints and the labels of the two triangles that are bordering the edge, leading, again, to an explicit topology. A separate array holds the coordinates of each vertex.
- A third structure has the edges as the basis. Each record stores the label of the “leading vertex” or node and the labels of all vertices that are linked to the node. The edges are arranged in clockwise order around the node, starting due north. There is a record for every node in the network. Another array stores the coordinates of all nodes. This structure is different from the other two in that the node records are of variable length and the topology is partially given implicitly through the sequence of neighboring edges. This is likely the structure that needs the smallest amount of storage and is fastest for searches across the network.

So what is a data structure such as TIN good for? First of all, to enter a set of data points into a structure with all the topological attributes gives the points accuracy and solidity. Second, a structure allows for the production of a variety of applications. Most operations that involve surface networks are searches across the surface with one or two of the dimensions (x , y , and height, or z) kept constant. The most frequent application is likely the creation of regular, rectangular grids, because a number of geographic information systems use TIN only for storage purposes, and as soon as something is done with the data, they are converted into the regular grid. These grids are the result of searches across the network with first the y dimension kept constant (horizontal lines) and then the x dimension (vertical lines). The drawing of contours means searching the network with the z dimension kept constant.

TIN is a structure on the way to a better understanding of terrain. Terrain is given by its rivers (channels) and ridges, and TIN is a very good approximation. “TIN is the thinking man’s DTM.”

TROLL, CARL (1899–1975)

Carl Troll was a German geographer who developed the concept of landscape ecology and made significant contributions to the study of high-mountain geography. He also served as president of the International Geographical Union from 1960 to 1964.

Troll was born in Bavaria, Germany, on December 24, 1899. He studied at the University of Munich, obtaining a doctorate in botany (1921) and another in geography (1925). Between 1926 and 1929, he undertook an extensive research journey through the Andes, during which he expanded on the concepts and research of his famous countryman, Alexander von Humboldt. His mountain studies were extended to Eastern and Southern Africa in the 1930s, and he was a member of the disastrous German expedition to Nanga Parbat in 1937. In 1930, he was appointed professor of colonial and overseas geography in Berlin. He moved to Bonn University in 1938.

His major achievements prior to the outbreak of World War II include the application of air photography to the analysis of landscape and formalization and adaptation of the concept of *Landschaftsökologie* (landscape ecology) to the study of *Hochgebirge* (high mountains); he applied the theory of altitudinal zonation to both the physical and the human and cultural aspects of mountains. However, his numerous publications in German made little impact on the English-speaking world until after the war. Yet

his treatise on patterned ground and frozen/periglacial phenomena at high altitude (1944) attracted U.S. military intelligence. It was republished in English translation (1948), thereby introducing his work to a worldwide readership.

At enormous personal risk, Troll protected his Jewish colleague, Professor Alfred Philippson, and his family from death in a concentration camp, through his contact with the pro-Nazi Swede Sven Hedin, a confidant of Hitler. After the war, Troll played a crucial role in reintegrating German geography into the international community, which was recognized by his election as president of the International Geographical Union in 1960. This led to acceptance of his proposal for an IGU Commission on High-Altitude Geocology in 1968, which he chaired until 1972, when ill health forced him to resign.

Troll used the vehicle of what developed as the “Mountain Commission” to interest international scholars in working together to expand mountain research worldwide. He attracted to the commission younger scholars, many of whom became leaders in the field, from Poland, Russia, Switzerland, Kenya, Japan, Canada, New Zealand, and the United States, as well as his own students and colleagues throughout Germany. Thus, he created a powerful research network. While he did not live to see this infectious concept and effective teamwork develop as a force for creating worldwide awareness about mountains, his life’s contribution provided the vital catalyst.

One of Troll’s special interests centered on the explanation of the factors affecting the position of the upper timberline worldwide. He also exuded an enthusiasm for terminology. His pre-war development of climate diagrams was outstanding for its time. In 1947, he founded and edited the quarterly journal *Erdkunde* (Earth Study). Many of his students became leaders in mountain research, including Olov Hedberg, Masatoshi Yoshino, and Frederich-Karl Holtmeier. His enthusiasm and charisma were overriding personality characteristics that did much to extend his influence. He died in Bonn in 1975.

TSUNAMI

The devastating tsunami in the Indian Ocean of December 26, 2004, alerted the world to one of the most terrifying natural phenomena on Earth. Few will forget the scenes of carnage and destruction wrought by the floodwaters as they swept across coastal areas. In fact, tsunamis have been known about for generations. The word *tsunami* is derived from the Japanese word meaning “harbor wave.” Tsunamis are frequently described as tidal waves; however, this view is erroneous, since they have nothing to do with tides. Tsunamis are generated by offshore earthquakes, submarine slides, and, occasionally, subaerial landslides that enter water bodies. Asteroid impact is an additional but much rarer mechanism. With the exception of asteroid impacts, the displacement of mass, whether through submarine sediment slides, the collapse of a volcanic edifice, or an earthquake that induces faulting of the seabed, leads to a large-scale displacement of water. Although most tsunamis are phenomena associated with the open ocean, some tsunamis can be generated within lakes and/or fjords due to rockslide failures. An attempt is made here to explain the processes of tsunami generation and propagation as well as what happens when tsunamis strike coastlines. A description is also given of how societies have responded to the perception of tsunami risk.

Tsunami Mechanics

When a tsunami is generated, the initial water movement is generally characterized by a rapid

drawdown and a lowering of the sea surface at the coast as the water moves into the area of seabed displacement. Thereafter, due to the build up of momentum, large kinematic waves are propagated outward from the zone of seabed disturbance. The waves travel across the ocean at very high velocities, often in excess of 280 mph (miles per hour), and possess very long wavelengths and periods. Tsunami velocity is mostly a function of water depth. Thus, as the waves approach shallow water, the wave velocity decreases, and the wave starts to break. At the coast, the tsunami flood level (run-up) is partly a function of the dimensions of the propagated waves but is also greatly influenced by the topography and bathymetry of the coastal zone, and as such, the waves can reach considerable elevations, causing widespread destruction and loss of life.

It is a mistake to think of a tsunami as a single wave. All tsunamis consist of a train of waves that can strike a coastline over time periods ranging from a few minutes to several hours. Often, a large incoming wave can be followed by a much smaller one. However, the backwash from the first wave can interfere with the wave motion of the second incoming wave. In many cases, this interference can act to amplify the dimensions of the second wave, causing it to increase in size beyond the first. From this description, it can be easily appreciated that the dimensions of individual tsunami waves striking a coastline are greatly influenced by wave resonance, refraction and diffraction effects, and local near-shore bathymetry.

Geography of Tsunamis and Warning Systems

The majority of tsunamis occur around the Pacific Ocean, but many are also known from other areas. The frequency of Pacific tsunamis is due to the high occurrence of severe earthquakes under or close to the seabed as a result of the subduction of oceanic crust adjacent to continental margins. Such geological processes are a characteristic feature of Japan, where there is a long history of devastating earthquakes and tsunamis. Between 1596 and 1938, the Japanese islands were struck by 15 major tsunamis. One of the worst of these took place on June 15, 1896, as a result of a large submarine earthquake centered under the ocean floor 93 mi. (miles) offshore. Since the epicenter of the earthquake was

located beneath the ocean floor, the inhabitants on nearby coasts, although they knew that an earthquake had taken place, were unaware that a dangerous tsunami had been generated.

Long before the tsunami of December 2004, the long history of tsunamis known to have affected coastlines bordering the Pacific Ocean led to the development of warning systems designed to alert the public in advance of the arrival of individual tsunamis. Following the Aleutian Trench earthquake and tsunami of April 1, 1946, together with the destruction of the Scotch Cape Lighthouse on Uminak Island and the devastation of Hilo, Hawaii, a case was made for the establishment of a tsunami warning system designed to protect life and property.

The Pacific Tsunami Warning System was developed by the U.S. Coast and Geodetic Survey (since 1970, the National Geodetic Survey) and has its center of operations on the Island of Oahu, Hawaii. The center, known as the Pacific Tsunami Warning Center (PTWC), became operational in 1948 and is linked to seismographic stations throughout the Pacific Basin. These provide data on Pacific earthquakes whose magnitude and epicenters make them tsunamigenic (capable of producing tsunamis). When an earthquake has taken place, the PTWC issues a tsunami watch to all receiving stations. The PTWC is also linked to more than 50 tide-gauge stations located throughout the Pacific. Any tsunami that has been generated by an earthquake is automatically recorded in the tide-gauges closest to the epicenter. If a tsunami has been detected, then the tsunami watch is upgraded to a tsunami warning. At this stage, the estimated times of arrival of the first waves are computed for all stations across the Pacific. Once the PTWC has issued a tsunami warning and has provided information on the times of arrival of the first waves, it is the responsibility of the local police, military, and civil defense agencies to decide on whether or not particular areas should be evacuated.

The accuracy of PTWC tsunami warnings is well illustrated by the famous Chilean earthquake and tsunami of May 21, 1960. Once the earthquake epicenter had been calculated and a brief study of local tide-gauge data had been completed, it was estimated that the velocity of the tsunami was 440 mph and that the tsunami would reach

the Hawaiian islands 14 hours and 56 min. (minutes) after its generation off the Chilean coast. The prediction was that the first wave would strike Hilo at 9:57 p.m.—it arrived 1 min. late.

In areas where the coast is located close to the epicenter of a tsunamigenic earthquake, the time that elapses between the generation of the tsunami and its arrival on the coast is often frighteningly short. For example, the first tsunami waves that struck the Chilean coast on May 21, 1960, arrived only 15 min. after the main earthquake shock. Similarly, there was only a relatively short time interval between the March 27, 1964, earthquake in Alaska and the arrival of tsunami waves at the coast. In both cases, loss of life occurred because the tsunami struck coastlines long before any PTWC warning could be given. In the case of the 2004 Indian Ocean tsunami, since the Pacific tsunami warning system did not extend as far afield as Indonesia, it was not possible to generate an instant warning to countries bordering the Indian Ocean. Instead, the first indications that a tsunami was likely to be generated came from the global array of seismic monitoring stations that were recording the occurrence of a huge earthquake beneath the Indian Ocean.

The presence of a tsunami warning system is essential for the Pacific region due to the large number of tsunamis that are known to have occurred. However, large tsunamis are also known to have taken place in other parts of the world, albeit less frequently. The Indian Ocean tsunami of 2004 is a good example of this, but there have been many other catastrophic events. In Europe, for example, the most destructive historical tsunamis were those that accompanied the Lisbon earthquake of November 1, 1755; the earthquakes in Sicily and Calabria on February 5, 1783, and December 8, 1908, respectively; and the Aegean Sea earthquake of July 9, 1956. Of these, the most destructive event was the Lisbon earthquake in 1755.

Prehistoric Tsunamis

In recent years, it has become increasingly clear that many large prehistoric tsunamis can be recognized in coastal sediment sequences, since such tsunamis frequently result in extensive coastal erosion and sediment deposition. The recognition that specific prehistoric tsunamis can be identified

using geological methods has provided the scientific community with very valuable information on the long-term frequency of tsunamis in particular areas of the world. For example, it is now known from geological studies along the Pacific coastline of the United States and Canada that a large, severe, destructive tsunami took place about 300 yrs. (years) ago. The geological evidence for this tsunami, associated with a large offshore earthquake, is supported by historical data from Japan, which suggests that this particular tsunami caused severe flooding throughout the North Pacific region. The recognition that such destructive floods associated with former earthquakes have taken place in the relatively recent geological past has alerted governmental organizations that if a similar event were to occur in the future, there would be widespread destruction in many of the cities that border the Pacific coastline of the United States and Canada.

Geological investigations have similarly shown that one of the most destructive tsunamis to have affected northwest Europe took place as a result of one of the world's largest submarine slides, which occurred in the Storegga area on the continental slope west of Norway. The second Storegga slide is believed to have occurred around 8,000 yrs. ago and involved the movement of about 400 mi.³ (cubic miles) of sediment and rock across the seafloor over a distance in excess of 300 mi. The magnitude of this slide is demonstrated by the movement of two blocks, 500 to 650 ft. (feet) thick and up to 6 to 20 mi. wide, that were transported as far as 125 mi. downslope, over seabed surfaces with average slopes of no greater than 1° to 2°. The tsunami generated by this landslide caused extensive flooding of coastlines bordering the Norwegian Sea and northeast Atlantic Ocean. For example, in the North Sea, flood levels reached up to 13 to 20 ft. above the contemporary high-water mark, while along the coastline of Western Norway and the Shetland Isles, the tsunami locally reached up to 30 meters (about 90 ft.) above former sea level (see photo).

Conclusion

The occurrence of this giant tsunami in prehistory teaches us an important lesson. It tells us

Section showing tsunami deposits at Maggie Kettle's loch, Sullom Voe, Shetland Isles. The tsunami deposits, exposed at the base of the section, consist of coarse sand deposits within which are balls (intraclasts) of peat caught up in the deposit during the passage of the tsunami wave. The tsunami that produced this deposit took place around 8,000 yrs. ago, when sea level in Shetland was approximately 65 ft. below present. The occurrence here of tsunami deposits at 33 ft. above sea level therefore implies a former tsunami run-up of around 100 ft. in this area.

Source: Author.

that there are few coastlines of the world that are not at risk from tsunamis. With this realization comes the need to be able to quantify tsunami risk. It highlights the need for tsunami scientists to be able to inform planners and politicians of the probability of occurrence of future destructive event in specific areas. This task is exceptionally difficult, since the database of

past events in history and in prehistory is always bound to be incomplete. Sadly, it has taken a catastrophic event such as that which occurred in 2004 to accelerate the pace of tsunami research to help find answers to these questions.

TSUNAMI OF 2004, INDIAN OCEAN

A major tsunami took place on December 26, 2004, which was the deadliest tsunami in recent history. On that fateful day, the tsunami left more than 225,000 people dead or missing, with many millions made homeless in a total of 11 countries. Indonesia, Sri Lanka, India, and Thailand were the hardest hit.

Regional Map of Tsunami-Affected Areas

28 December 2004

This map illustrates coastal areas under 20 meters in elevation, as shown in bright yellow. This low-lying coastal zone is not a direct indication of areas affected by the 26 December 04 Tsunami—only those areas which may have suffered damage. For example, although Bangladesh is almost entirely under 20m in elevation, extensive swamps and limited settlements along the coast resulted in few casualties.

Source: Courtesy of UNOSAT, the UN Institute for Training and Research (UNITAR) Operational Satellite Applications Programme, implemented in cooperation with the European Organization for Nuclear Research (CERN). Map based on data provided by International Charter Space and Major Disasters.

The tsunami was caused by an offshore (undersea) earthquake of magnitude 9.2 that was triggered along an area of plate collision where the India Plate, an oceanic plate, is being subducted beneath the Burma-Sunda plate across a subduction zone in the area of the Sunda Trench. The epicenter of the 9.0-magnitude quake was under the Indian Ocean off the western coast of Sumatra, Indonesia. The earthquake was associated with the rupture of the seafloor along a length of 1,000 km (kilometers; 620 mi. [miles]). Along this zone, the land surface was displaced both laterally and vertically by several meters. This event led to the sudden displacement of the overlying ocean water and the production of the tsunami.

Along the coast of Northern Sumatra, tsunami waves up to 30 m (meters; 100 ft. [feet]) in height destroyed everything in their path. The tsunami traveled across the Indian Ocean, causing devastation along coastlines as far as away as Somalia, Kenya, and the Maldives. Some of the most destructive flooding took place along the coasts of Thailand, Sri Lanka, and India, where many thousands of people lost their lives and many more lost their livelihoods.

TUAN, YI-FU (1930–)

The works of the Chinese American geographer Yi-Fu Tuan represent a major contribution to geographical scholarship. His huge corpus of writings reflects a humanistic-geographical approach that in the 1960s and 1970s went against the grain of positivistic studies that were reflected in the so-called quantitative revolution.

Tuan was born in Tanjin, China. The work of his father, a diplomat, required the family to move frequently between continents, and Tuan was educated in China, Australia, Britain, and the United States. For much of his early life, therefore, his “home” was rarely static; he never lived in one place for more than 5 yrs. (years) until he was 38 yrs. of age, when he became based at the University of Minnesota. He completed his academic career at the University of Wisconsin but has continued writing and researching. Tuan sees himself as a “cosmopolite” and, on balance, feels that such a life is better than the “safeness of the hearth.”

Tuan’s post-high school education commenced at Oxford University. He gained his undergraduate degree at the age of 20, and at Oxford, he developed a penchant for physical geography, a field that he developed further in his postgraduate studies at the University of California, Berkeley. His studies focused on pediments in southeastern Arizona, with his fieldwork undertaken between 1953 and 1955.

The bulk of Tuan’s work may be described as humanistic or phenomenological geography. His writing has been inspired by the studies of the American scholar John Kirkland Wright and his notion of “geopietry” (meaning the relationship between humans and nature) and those of the conservationist Aldo Leopold. Carl Sauer and J. B. Jackson were other inspirations. Tuan is well-known for his use of an eclectic range of authors, and he is willing to draw on literary as well as academic sources, both of which have influenced his intellectual development.

It can be argued that Tuan’s reputation was built on two key books that have been used and applied over the past 30 years or more. The first of these is *Topophilia* (1974), a path-making work that focused on the links between human beings and place. It is regarded by his peers as a “classic

in human geography,” though it is erroneously believed that he coined the neologism *topophilia* (W. H. Auden and Gaston Bachelard used the word before him). However, there is no doubt that he popularized a concept that has been subsequently applied to a wide range of themes that deal with the “sense of place,” or the cognate idea of *genius loci*. A study of “negative” senses of place (“topophobia”), *Landscapes of Fear* (1979), is less well-known. He returned to the power of place in *Space and Place* (1977), another definitive work that sees place as inhabited space.

Although Tuan is considered by some as an academic “outsider,” it is possible to see in his work illuminations of writing by Michel Foucault and other eminent scholars. For example, Tuan’s *Segmented Worlds and Self* (1982) stresses the changing spatial structures in society in relation to society’s varied forms of control. Later work saw Tuan define geography as a “moral science”; for example, in *Dominance and Affection* (1984), perhaps his most pessimistic book, his foci are pets and gardens. In this fascinating work, he wrestles with the possibility that affection—indeed, love—may be seen as an extreme form of domination.

Two terms characterize Tuan’s oeuvre: *humility* and *vitality*. He continually seeks to explore the “good life.” As he seeks it in many of his works, he draws extensively on literature and self-reflection. To be sure, he has had his critics (though they are few and far between), yet he returns and modifies his examples by testing and editing his findings.

Tuan is a scholar who wishes to engage with his readers. Hence, in *Dominance and Affection*, facts and ideas are carefully, but with responsibility, displayed and explored, and the author necessarily focuses further on a specific problem and its detailed examination. Additionally, for many years, he has disseminated weekly letters to his colleagues and students that provide a “verbal outlet” to his thoughts.

Tuan has published a large number of papers and books, most of which have been acclaimed. His works *Escapism* (1998) and *The Good Life* (1986) are examples where taken-for-granted subjects are explored through Tuan’s philosophical lens, through which he seeks understanding and appreciation without being seduced by surface phenomena. Indeed, he regards a humanistic

approach as seeing ordinary objects afresh, delighting in them for what they are and, as they appear, excavating hidden relations and meanings and then, in conclusion, presenting surfaces and depths—the seen and the unseen.

Tuan’s work has been appreciated in a wide variety of disciplines, including geography, history, architecture, psychology, philosophy, and sports studies. He has received many honors, including the Callum Geographical Medal from the Association of American Geographers and the Laurat d’Honneur of the International Geographical Union.

TURNER, BILLIE LEE, II (1945–)

Billie Lee Turner II helped reinvigorate a science orientation to human-environment relationships, initially by steering cultural and historical geographical topics shared with anthropology into the

subfield of cultural ecology and subsequently by leading the development of land change and sustainability science. Of his scholarly contributions, including the role of geography as a human-environment research endeavor, three deserve special consideration. First, his field research in Mexico and Middle America paved the way for a new understanding of ancient Mayan human-environment relationships by demonstrating the various cultivation and landscape practices employed by this civilization. His work provides the basis by which questions on the rise and fall of the Mayan civilization must be set. Second, he and his students helped develop the induced intensification thesis of smallholder cultivation in the contemporary tropics, demonstrating how outcomes linked to both Boserup and Malthus are possible. This thesis demonstrates how the ambient environment alters the outcomes of different levels of pressures on land use and how household response to these pressures is predicated on a fusion of market and subsistence factors. Third, he has been an international leader in the development of global environmental change and sustainability research, through the lens of what has become land change science. His team of researchers has advanced remote sensing and modeling assessments of tropical deforestation, demonstrating that vulnerability must address a coupled human-environment system and pointing the way toward the research challenge of discovering sustainable land architectures.

Turner earned his PhD from the University of Wisconsin–Madison in 1974. In 1980, he joined the Graduate School of Geography, Clark University, where he remained for the next 28 years, mentoring 40 PhD students and serving as the Higgins Professor of Environment and Society. For several years, he was director of Clark's Graduate School of Geography and the George Perkins Marsh Institute. He served as a fellow at the Center for Advanced Studies in the Behavioral Sciences (Stanford) and was elected to the National Academy of Sciences (1995), American Academy of Arts and Sciences (1998), and Massachusetts Academy of Sciences (2008). In 2008, he became the Gilbert F. White Professor of Environment and Society, School of Geographical Sciences, Arizona State University.

TYPHOONS

See [Hurricanes](#), [Physical Geography of](#)

TYPGRAPHY IN MAP DESIGN

Typography in maps refers to symbols and signs in maps. Since maps are graphical representation of spatial relationships that essentially reduce the permutations of space into a two-dimensional topological construct, the role of typography is limited to labeling points, arcs, and polygons (referred to as features) with appropriate and efficient form, style, and weight factors.

In 1990, John B. Harley redefined maps as more than mere efficient representations of physical surfaces. Through a postmodernist reinterpretation of map typography, Harley viewed maps as representations of power. Thus, maps have joined the ranks of other graphical pursuits, such as architecture and design, that encounter such ontological

issues. The impact on typography has been evident ever since the stability of ideas, as Plato imagined it, was challenged in the past two centuries with concepts such as semiotics and deconstruction. Ferdinand de Saussure (1857–1913), a Swiss professor of linguistics and a contemporary of Sigmund Freud, Émile Durkheim, Charles Darwin, and Karl Marx, revolutionized the field by introducing the concept of semiotics. The broader epistemological basis for semiotics is contained in structural and poststructural philosophy.

The history of symbols and signs since antiquity has evolved separately in the fields of art, architecture, and cartography, but there are signs of convergence, at least epistemologically.

Since all relevant information cannot be printed on maps, the field of cartography developed a sophisticated ontology. The way the cartographer represented symbols and signs depended on what was viewed as important and appropriately signified the signifier (semiotics). Therefore, the symbol for “north” is interpreted as the direction north, but the orientation of north (up, in most maps) is historically a result of maps mostly constructed as a cultural legacy of the Northern Hemisphere. Therefore, the semiotics of typography is in what it implies and is more complex than functional issues such as what it represents.

With the advent of computer cartography and the possibility of dynamic labeling (through artificial intelligence and haptic manipulations such as “zoom” and “mouse over”), a strict cartographic hierarchy need not be followed; instead, map

typography can be dynamically “programmed” to satisfy a large community of map users. The resulting flexibility does not eliminate the complex power structure that Harvey implied earlier but allows for improved efficiency. With artificial intelligence algorithms, the complex demands on map typography can now be better handled than was possible in the earlier era of analog maps.

Since traditionally, map making and mapping software have usually represented feature-based maps (i.e., maps that contain discrete and finite elements that can be represented by points, arcs, and polygons), the representation of “fields,” or continuous objects, has been neglected. However, the dynamic representation of time and space through digital technology now allows for field-based typography. Examples include traffic and weather simulation, as seen in some geographic information software such as Transmodeler.

UNDERDEVELOPMENT

Underdevelopment refers to not only a theory but also an economic process and a condition described by radical views of development. The theory is rooted in structuralist Marxist ideas and is associated with the dependency school of development, which is critical of North-South relations. This entry first gives a description of underdevelopment. It then traces the historical evolution of thinking concerning radical underdevelopment theory, highlighting important thinkers, and offering descriptions of the various iterations of theories of underdevelopment. Finally, important critiques of underdevelopment and the dependency school are discussed, concluding with the state of ideas of underdevelopment today.

The dependency school of thought is commonly understood to be a response to the failure of modernization theories of development in the 1950s and 1960s, notably in Latin America, particularly the agenda of the United Nations Economic Commission for Latin America (ECLA), as well as the crisis of orthodox Marxism. ECLA intellectuals argued that development and underdevelopment are the result of the same process. In contrast to modernization theory of development through comparative advantage in international trade, these scholars argued that the colonial integration of Latin American, African, and Asian economies into the global capitalist

system had led to outward-oriented development dependent on the export of primary sector commodities. This process created a center and a periphery in the global economy; a system in which peripheral economies are systematically disadvantaged not only by the geographic divide in production and trade but also by the lack of technology transfer that would normally occur with the development of a capital goods or value-added industrial sector, where the difference between the value of the factors of production, including labor and capital goods, and the final sale price of a good, accrues to the contributor. Developed largely by Third World intellectuals, it challenged the ideas of modernization theory dominant in the 1950s and 1960s, offering a counternarrative to First World narratives of history, economics, and development.

Origins and Evolution

Underdevelopment refers to an economic condition characterized by undiversified primary sector production for export (usually agriculture), wide income disparities typified by a small upper class where wealth is concentrated, and a small internal market. The state of underdevelopment, in which poorer nations have market relations with industrialized countries, must be distinguished from those without development, which do not have market relations with industrialized countries. Discussions of underdevelopment typically

The Crocodile River flows through the biggest slum of Freetown, Sierra Leone: Kroo Bay.

focus on the spatial scale of the individual state and its trade relations with developed economies. Two categories of underdeveloped states are distinguished: (1) those that were nation-states before they were integrated into the world economy and (2) those that transitioned from colonies into states at independence but without any change in their social or economic relationships with their ex-colonial administrators. In either case, underdevelopment is a historical legacy of colonialism and a process directly attributed to the historical spread of capitalist structures: The center-periphery (or metropolis-satellite) relations that were forged during colonialism resulted in formal colonies depending on developed countries to purchase their raw materials. Thus, any growth or development in countries dependent

on raw materials depends on expansion of the market in developed countries.

Radical underdevelopment theory and the dependency school of development have their origins in the early 1950s. As early as 1950, the Argentine economist Raúl Prebisch, head of ECLA, recognized the inadequacy of the conventional global division of labor, in which regions such as Latin America produced raw materials and commodities for export to developed regions such as North America and in turn received manufactured goods from these regions. Prebisch argued that the dependence on commodities and raw materials exports was at the root of the poor economies' problems and that capital accumulation was impossible under those conditions because it was inhibited by disadvantageous terms

of trade, that is, exports of low-priced foods and raw materials and imports of expensive manufactured goods. In response to this realization, Prebisch promoted a new strategy for Latin American economies. The strategy was based largely on protectionism and import substitution industrialization, but it also retained a focus on the export of raw materials and food commodities. Even as integration into the world economy was seen as detrimental to the development of Latin American economies by ECLA, the argument for continued focus on raw materials export was that it would finance the importing of capital goods, supporting economic growth through technology transfer. Governments would play an active role in implementing the ECLA strategy.

After a period of growth in Latin America in the 1950s, nation-states participating in the ECLA program faced economic stagnation attributed to the failure of the ECLA strategy. It essentially proved overly ambitious and inadequate for the problems facing Latin America and other poor regions, as it did not attack structural disadvantages but, instead, worked from the assumption that industrialization would fix other obstacles of development in the developing economies. In fact, import substitution industrialization fell short of producing a favorable balance of trade for underdeveloped countries because it neglected the diversification of the export sector from raw materials and commodities.

The failure of the moderate ECLA strategy prompted more radical thinking on development in the 1960s among Latin American intellectuals. At the same time, Latin America was experiencing a crisis of orthodox Marxism. The Cuban and Chinese revolutions inspired the theory that societies did not have to pass through the requisite stages of bourgeois revolution and then socialist revolution, as Marxist theory asserted; instead, they could proceed directly to socialist revolution without the evolution of the bourgeoisie. This neo-Marxism also provided the basis for the radical critiques of the ECLA program and shifted the thinking of Latin American development theorists in the 1960s from economic structures to inclusion of the social implications of the center-periphery division of labor.

Andrew Gunder Frank developed key critiques of the modernization school of development that

significantly contributed to the development of dependency theory and thinking about the processes and implications of underdevelopment. First, modernization theory is based on the experiences of First World countries, which never experienced colonization—a process that effectively set in place the structures of Third World economies. Instead, modernization theory attributes underdevelopment to internal factors such as culture or a lack of investment. Frank offered an external explanation in place of the internal one, with the reasoning that societies such as China were advanced before experiencing colonization, which effectively reversed these societies' development. Frank further theorized the mechanisms of underdevelopment, proposing a metropolis-satellite model in which complex systems of economic surplus extraction and transfer span the globe, flowing from Third World economies to First World countries. These critiques led Frank to a series of hypotheses that theorize “the development of underdevelopment”—a famous term coined by Frank that signifies underdevelopment as a historical process rather than a normal or inevitable condition of Third World societies. Essentially, Frank hypothesized that satellites that had the closest historical relationships to metropolises are the most underdeveloped and that there is a direct correlation between their relationship with the metropolis and the extent of their underdevelopment. Furthermore, reintegration of satellites into the economic system after a crisis reverses any previous industrial development those countries might have achieved. Frank also played a key role in communicating and disseminating the ideas of radical underdevelopment theory and the dependency school to the English-speaking world, where it resonated with the ideas of radical young researchers who were in the midst of overturning their own establishment.

Cardoso and Faletto added nuances to the radical underdevelopment theory in the early 1970s, further critiquing modernization theory's modern-backward dichotomy and adding internal factors such as national-scale class relations to the external explanation. They argued that the dominant socioeconomic class imposes through political action a set of social relations that is most in its own economic interests and that elites' relationship to international metropolises

facilitates the flow of wealth toward the metropolises. In other words, the internal economic relations between the classes, as well as elites' ties to the core economies, actually limit political action and thus restrict social change. Hence, polarization between the classes can occur internationally, regionally, as well as nationally—the result of the historic evolution of capitalism; however, how it has played out in each country depends on the economic and class structure of the specific country and the elites' relationships. The evolution of oppositional ideas and theories of development was not restricted to Latin America; scholars such as Samir Amin in the early 1970s drew from the experience of African societies and their struggles for sovereignty, creating further iterations of theory under the rubric of neocolonialism.

Critiques of Underdevelopment and the Dependency School

Critiques of the radical underdevelopment theory and the dependency theory (often considered synonymous) address a variety of issues. First, the primary unit of analysis used by *dependistas* (early proponents of the dependency theory) is the nation-state, which was not the sole actor and is arguably no longer the primary actor in economic globalization. Instead, transnational corporations and international institutions bring with them distinct dynamics of domination, even as they continue the work of extracting economic surplus from underdeveloped countries. Second, the dependency school cannot explain Third World capitalist development; in fact, it effectively ignores it. A third critique of the underdevelopment and dependency theory is its strict developmentalist approach, arguing that societies had to go through some kind of socialist revolution followed by a process of autonomous development. Another important critique of underdevelopment spoke to its oversimplification of metropolis-periphery relations: It did not acknowledge that even as the core economies extracted surplus from Third World countries during the process of underdevelopment, the situation was often much more complex in that capital often flows in the other direction as well, that is, from the metropolis to the periphery. For example, transnational corporations invest in

industrialization and production infrastructure since they have an interest in promoting development as it opens new markets for their goods and services. The problem of dependency persists, however, since developing countries depend on developed countries for technology and investment. Put in other terms, development and dependence exist simultaneously, and the exact manifestations are varied and complex, in contrast to the simple scenario presented by dependency theorists.

Current State of Underdevelopment and the Dependency School

Although theories of underdevelopment and dependency are often considered today to be defunct or obsolete, it must be recognized that the evolution of thinking on underdevelopment took place in the context of the Cold War. The Cold War was a period of instability and turmoil in which intellectual opposition was part of wider political and social opposition movements that fed into the development of oppositional thinking that is still relevant today as underdeveloped societies continue to struggle against foreign economic, social, and cultural domination. Contemporary issues, including the foreign debt crisis, only reinforce the argument that the basic precepts of underdevelopment still hold and can be further developed to integrate new developments and phenomena of contemporary globalization. Furthermore, scholars such as Milton Dos Santos in the late 1990s pointed out that underdevelopment and dependency theories are still given much scholarly attention and underdevelopment discourses are still widely used, especially in Third World intellectual circles. Others argued that the ideas proposed by scholars of oppositional theories in the 1960s and 1970s are still relevant to today's world as part of a larger movement to revitalize the inclusion of oppositional narratives of economics and history, especially in light of the contemporary dominance of neoliberal ideas.

UNEVEN DEVELOPMENT

Uneven development is a general term for the measurement and explanation of spatial patterns of variation in the quality of life among human beings, or in a more restricted sense within Marxist theories, the concept is a fundamental and inescapable part of capitalism. The definitions of *development* are varied and contentious. Even given a particular definition, the patterns observed will vary widely depending on the chosen spatial scale. It is more challenging still to uncover the causes of any pattern and to situate these causes within a theory with explanatory power for larger areas and longer time periods. This entry discusses the definition and measurement of uneven development, the problem of scale, neo-Marxism and neoliberalism within the context of uneven development, and the subaltern and current trends.

Geographers and other social scientists have tended to approach uneven development through the lens of theories that, despite their varied emphases, overlap considerably: world-systems theory, dependency theory, neoliberalism, and, especially, neo-Marxism. Each approach grapples

with the question “To what degree is uneven development an inevitable, even desirable, consequence of the spatially unequal comparative advantages inherent in a global capitalist system?” Another question is, “To what degree is uneven development a consequence of physical geographic endowment, and to what degree is it due to the chance contingencies of history?” Since the refutation of environmental determinism in the 1920s, this second question is asked less often; it is now generally taken for granted that uneven development is a complex intertwining of both factors. The subfield of cultural ecology, influenced by anthropologists such as Eric Wolf, has continued to examine the particulars of this intertwining, as have geographers such as Philip Porter and Eric Sheppard and, for a broader audience, Jared Diamond.

Work since the 1990s has tended to question assumptions regarding structure and agency and has inquired how spatial disparities may be mitigated, or redefined, by individuals or groups often considered its passive victims—the so-called subaltern. Postcolonial and Marxist geographers observe how neoliberal experiments have played out in various regions of the world and have reworked some Marxist ideas to better explain uneven development in the rapidly globalizing 21st century.

Defining and Measuring Uneven Development

Except with case studies for the smallest areas, much geographic analysis depends on the availability of spatial data. The most commonly used measure is gross national product (GNP)—the total final output of goods and services produced by an economy—and its derivatives, especially GNP per capita. While in some cases, this may be quantified for subnational regions or supranational blocs, by definition GNP privileges the nation-state scale. GNP may be considered as a static measure (e.g., to compare “more developed” and “less developed” nation-states) or as a dynamic rate of change (e.g., to identify “rapidly developing” nation-states).

Even if we accept “income” as an appropriate proxy for “development,” there are many practical problems with this measure, such as its failure

to capture the informal economy, which is often considerable in developing nations. Another option is the Human Development Index (HDI), popularized by the United Nations Development Program, which combines life expectancy at birth, adult literacy, mean years of schooling, and income sufficiency for an adequate quality of life.

Some studies use other variables such as human right indices to analyze development. Most, however, assume that income is a fairly reliable proxy. This assumption may be explicit, as in studies based on world-systems theory, or implicit, as in studies based on capital flows and in most feminist work. While they may agree on little else, Marxist geographers and neoliberal advocates both tend to rely on income as a useful indicator. The few who contend it directly are those, often postcolonialists, who question the entire idea of development.

On occasion, “development” has been examined as a sort of industry unto itself. The Colombian anthropologist Arturo Escobar has shown how the identification, professionalizing, and institutionalizing of development “problems” by rich nations and their allies in poorer ones increase the power of both at the expense of those they claim to serve. Escobar advocated indigenous, autonomous social movements and localized, place-based strategies of development, a strategy compatible with certain geographic methods such as participatory research mapping.

The Problem of Scale

In one way or another, analyses of development study human beings, individually or grouped at various spatial scales. It could be argued that ever-increasing mobility makes it less important to map and analyze people, and groups of people, as if they were fixed points in space. However, three facts work against this argument. First, labor and, to a lesser degree, capital and ideas are less mobile than is often assumed; nation-state boundaries are still generally strong barriers, and those who do migrate are often considered “temporary” workers without full rights in their host nations. Second, many geographers analyze “space” in a sense that goes beyond mere coordinates on the Earth’s surface; for example, Ashraf Ghani sees space as an

“arena of represented practices,” where social constructions of gender may underscore less apparent inequalities of development. Third, some geographers (often “transnationalists”) study mobility itself as a vector for both amelioration and worsening of uneven development at different scales.

At the scale of nation-state blocs, the groundwork for much geographic study of uneven development was laid by world-systems theory, formulated in the 1970s by the sociologist Immanuel Wallerstein. World-systems theory examines the economic conditions of nation-states within the global system, which in its most basic form is seen as having a core (the most developed nations, with 20% of the world’s population but 80% of its GDP), a semiperiphery (Mexico, the Newly Industrializing Countries, and the “BRICs,” i.e., Brazil, Russia, India, and China), and a periphery (including Africa, the poorer parts of Asia, Oceania, Latin America except for Mexico and Brazil, and the Caribbean). This world system originated in 16th-century Europe, when the core was England, Northern France, and the Netherlands, although its membership has changed over time. A global labor pool is linked through commodity chains, and in the periphery, labor is generated through some threat of force. Even if shirts are made in the Honduras of cotton from India, the patent holders, the designers, the marketers, and the ultimate controllers of labor and capital investment are mainly in the core. In these and other ways, world-systems theory supports Marxist assertions.

World-systems theory is well suited for examining supranational political-economic entities in the core (such as the European Union), as well as international trading blocs, such as the North American Free Trade Agreement (NAFTA), which facilitate the flow of goods and capital in and out of the core. It helps explain why the nation-state is becoming less important in the core (e.g., the United States now shares economic dominance with countries such as Japan) and in the periphery (where ethnic ties often dominate, reinforced through 19th- and 20th-century European colonial practices), while the nation-state continues to be strong in the semiperiphery (in large-population “emerging markets” such as Mexico).

Geographic studies directed toward other scales are consequently less top-down or Eurocentric than world-systems theory. Some multiscale studies have their roots in dependency theory, which acknowledges relationships between local elites and dependents—even between village leaders and other villagers—up to and including global nation-state blocs. At each level, unequal terms of trade lead to self-perpetuating unequal exchange, another basic tenet of Marxism.

Subnational regional patterns of uneven development have been examined throughout the world, including in Mexico (the indigenous south vs. the developed north), England (the richer southeast vs. the poorer north), and China (the industrialized coast vs. the impoverished interior). The Brazilian economist (and later president) Fernando Cardoso has influenced many such studies. Often, more developed regions are centered on urban centers of finance, academic research, or government, themselves often located in former or current places of commercial trade (e.g., ports or important international borders) or colonial loci of centralized bureaucracy.

The Marxist geographer Neil Smith (2008) wrote that “city building has become a motive geographical force of capital accumulation, a source of massive surplus value production” (p. 263), especially in Asia, in part fueled by massive rural-to-urban migration. Recent urban geography work builds on earlier studies of uneven development (many contrasting inner cities and suburbs) to focus on alternative models in developing nations as well as on gentrification.

Neo-Marxism, Neoliberalism, and Uneven Development

The writings of Marx contain little about the spatial implications of the theories he espoused, but throughout the 20th century and into the 21st, Marxist geographers developed a large body of literature on the subject. To explain uneven patterns of development, these writers have departed from the teleological predictability that infuses orthodox Marxism. Instead, they emphasized how Marxism regards the global capitalist system as a zero-sum game, and consequently, we should expect to find entrenched spatial concentrations

of “winners” and “losers.” This idea is paralleled in world-systems theory, which argues that increasing linkages tend to perpetuate inequalities rather than ameliorate them, as neoliberalist thinkers contend. Also, as in world-systems theory, the nation-state is seen as having played a key role in protecting and expanding systems of surplus extraction.

Since the 1980s, Neil Smith and David Harvey have been the most prominent neo-Marxist geographers. In their works, capitalism seeks to equalize the conditions of production over space while simultaneously taking advantage of, and so accentuating, those differences—as capital “seesaws” between the developing world (the source of cheap raw materials and cheap labor) and the developed world. This view helps explain recent phenomena such as the global rise in remittances and the decrease in food security in the late 2000s, as once self-sufficient countries such as Mexico and Nigeria devote ever-increasing amounts of land and labor to the production of foodstuffs for export.

Spatial patterns of uneven development are perpetuated because capital, even in the era of instantaneous global financial transactions, still seeks to “park” itself somewhere; capital can only circulate if some part of it does not. This process can be analyzed at many scales. The geographer Don Mitchell analyzes specific small landscapes as loci of regional and global inequalities. A strawberry farm in California, for example, is a fixed node in space where capital is invested; the products of that landscape, and the landscape itself, hide the unjust labor conditions that allow it to exist. Others examine subnational regions, showing how, for example, the continued importance of face-to-face contacts influences corporate decisions. At the world-system scale, Federal Reserve Chair Ben Bernanke suggested that money generated during the real estate bubble in Japan in the 1990s (during a downturn in southeast Asia) eventually found its way into the U.S. debt market, thus helping set the stage for the economic collapse of 2008.

The global slowdown of the early 1970s, along with the expanded foreign debt of semiperipheral countries such as Mexico and Thailand in the 1980s, set the stage for neoliberal experiments in the 1990s. Neoliberal theory contends that uneven

development can be ameliorated by removing state regulation and barriers to free flow of goods, capital, and (sometimes) labor. Marxist geographers such as David Harvey argue that this has made some countries more internally uneven than before, while separating the semiperiphery into two groups: (1) those that have generally benefited (e.g., China and India) and (2) those that have not (e.g., Mexico).

The neoliberal experiment has faced practical difficulties, including the following: (a) it may be perceived as a disguise for accelerated capitalist accumulation to benefit developed nation-states and local elites, (b) the nation-state bureaucracy and power structure often remain as strong as before, and (c) the “temporary” hardships produced by “structural adjustments” have led to many rightist governments of the 1990s being replaced by leftist ones in the 2000s. In the 2000s, most neoliberal advocates have recognized these deficiencies while remaining optimistic that the underlying principles are sound.

The Subaltern and Current Trends

To what degree do the causes of uneven development come from privileged, centralized decision makers (e.g., supranational organizations such as the World Bank, rich nation-states, and transnational corporations), and to what degree can they be mitigated by the less transparently powerful “subaltern” entities (e.g., poor nation-states, “progressive” nongovernment organizations, and individuals)? As Marxism is rooted in the potential for dynamic disequilibrium and revolt in human societies, neo-Marxist thought on uneven development has found commonalities with postcolonialist and post-structuralist thinkers such as Homi Bhaba, who criticize both world-systems theory and dependency theory for their failure to acknowledge the power of the subaltern in intellectual, cultural, and sometimes political realms.

In part, such criticism is a reaction to the assumptions of modernization theory, which in geography grew out of Eurocentric studies of innovation diffusion in the 1960s. Many geographers now recognize how the Internet, for example, permits relatively low-cost links to be formed between people in the global periphery

and global NGOs; others, however, point out that even Internet access is spatially uneven.

One implication of this turn from Eurocentric attitudes is a revised understanding of history. Eric Wolf showed how, well before the 16th-century European global expansion, multiscale spatial inequalities in development existed in Asia, Africa, and the Americas through the buildup of hegemonic political and military systems and long-distance trade linkages.

“Development” can be thought of as an unfolding of something that was in some sense there to begin with (this is its etymological root meaning) or instead as the intervention of an outside force on a region and its people. Geographers today consider local actions and global processes as mutually constitutive. While flexible accumulation and globalized commodity chains and capital flows allow development to happen in some places where it had not occurred before (e.g., Ireland and parts of India and China), it still must happen in some places and not in others.

Discussion of uneven development continues among neo-Marxist geographers, as well as others who explore the complexities and contradictions of postcolonial globalization. At the nation-state scale, these complexities include the incomplete adoption of neoliberal tenets by countries such as Mexico (where deregulation of land and water markets has been contested) and the perpetuation of extractive and elite-benefiting practices by some postcolonial governments (e.g., Indonesia) with roots both in European colonialism and before it. Geographers of uneven development are well positioned to analyze the global economic downturn of the late 2000s, wherever it tends to reduce spatial inequality, so as to “lower all boats” equally while maintaining patterns, or to exacerbate inequalities as capital flees from a periphery now with reduced options for local and regional development.

UNITED NATIONS

The United Nations (UN) is an international organization created in the aftermath of World War II to promote peace and prosperity among and within nations and states. Its formal existence began on October 24, 1945, with the ratification of the UN Charter by China, France, the Soviet Union, the United Kingdom, the United States of America, and other signatories.

The UN is generally considered to be the successor to the League of Nations, which was established in 1919 to promote international cooperation, peace, and security. As the league's international role faded in the 1930s and 1940s, various national governments agreed to form a new organization. They met in San Francisco in 1945 to draw up the UN Charter. As of December 2009, the UN had 192 member states; Montenegro (which joined in 2006) is its newest member.

The charter is the constitution of the UN, detailing rights and obligations of member states and establishing and describing UN organs and procedures. According to its charter, the purposes of the UN are the following:

- (1) to maintain international peace and security . . .
- (2) to develop friendly relations among nations based on respect for the principle of equal rights and self-determination of peoples . . .

(3) to achieve international cooperation in solving international problems of an economic, social, cultural, or humanitarian character, and in promoting and encouraging respect for human rights and for fundamental freedoms . . .

(4) to be a centre for harmonizing the actions of nations in attaining these common ends. (UN, 2005, p. 5)

The following principles guide the work of the UN (2004, p. 5):

1. All its members have sovereign equality.
2. All members are to fulfill in good faith their Charter obligations.
3. They are to settle their international disputes by peaceful means.
4. They are to refrain from threat or use of force against any other state.
5. They are to give the UN every assistance in any action it takes in accordance with the Charter.
6. Nothing in the Charter is to authorize the UN to intervene in matters that are essentially within the domestic jurisdiction of any state.

Countries that accept the obligations and responsibilities entailed in the UN Charter may apply for membership; the General Assembly admits new members on the recommendation of the Security Council. The charter also allows for expulsion of a member, but this has never occurred.

The UN has six principal organs: (1) General Assembly, (2) Security Council, (3) Economic and Social Council, (4) Trusteeship Council, (5) International Court of Justice, and (6) Secretariat. There are also numerous UN programs and funds (e.g., UNICEF [United Nations Children's Fund], UN-Habitat, UNDP [United Nations Development Programme]), specialized agencies (e.g., UNESCO [United Nations Educational, Scientific, and Cultural Organization], WHO [World Health Organization]), and thousands of nongovernmental organizations associated with the UN in a variety of ways.

These UN organs are heavily dependent on data, methods, theories, topics and practices, many of them specific to the field of geography.

United Nations headquarters in New York City

Like the discipline of geography, the work of the UN is broad in scope but integrative in nature, with an emphasis on education and capacity building. The work requires definition and understanding of place and its dimensions.

Since the UN is run for and by the people of the world, data come from all over the world, are qualitative and quantitative in nature, and are subject to technological change. For example, originally, country tabulations of censuses used to be collected in filing cabinets, but today sophisticated

databases, ETL (extract, transform, and load) processes, and Web-based exchange with statistical offices are common. The demographic data collected by the UN, for example, are used for global population projections—the only such projections in the world still regularly produced based on a consistent set of methods, tools, and data. These data are used for a worldwide demographic assessment of past, current, and future demographic trends.

Cartography is also crucial to the work of the UN and has undergone significant technological changes. For example, maps are essential to peacekeeping missions as well as to aid organizations, which need to know where to distribute food for the needy or where to vaccinate sick children. Often, the UN itself is the principal authority over the definition, collection, and distribution of worldwide data on various topics (see, e.g., the Principles and Recommendations for Population Housing Censuses [UN, 2008] or the Technical Reference Manual for the Standardization of Geographical

Names [UN, 2007]). Several UN entities provide technical expertise, logistical support, and material aid intended to strengthen the capabilities of member nations in these fields.

The UN Charter lists maintaining international peace and security as its primary goal. The UN monitors and assesses global political developments and actively engages in peace-making and preventive diplomacy. The charter also entails work on economic and social development and humanitarian affairs, all of which

involve geographical matters. Sustainable development, climate change, urbanization, and HIV/AIDS are among the core issues on the UN's current agenda. At the 2000 Millennium Summit, member states reaffirmed their support for the UN and declared it as the focal point through which all governments should seek to realize common goals of peace, security, and development. The eight Millennium Development Goals, supported by a number of specific and attainable targets, were agreed on as the framework to achieve common development goals: (1) the eradication of poverty; (2) universal primary education; (3) the promotion of gender equality; (4) reductions in child mortality; (5) improvements in maternal health; (6) combating HIV/AIDS, malaria, and other diseases; (7) ensuring environmental sustainability; and (8) developing a global partnership for development.

The work of the UN is ultimately defined by the world's people. Their governments vote on resolutions, in the General Assembly or the Security Council, affecting lives all over the world. Over the years, nongovernmental organizations have also become partners in the day-to-day activities of the UN, forming a "valuable link to civil society" (UN, 2004, p. 13). The staff of the UN (generally referred to as the UN Secretariat) come from all over the world. Personnel are recruited to meet certain region- and country-specific quotas; they speak at least one of the official six UN languages and have taken an oath to be solely responsible to the UN and not to any government or other authority external to the organization. Although much of the work of the UN is political, the critical inputs are often scientific, based on common data, methods, theories, and topics, many of which are intimately related to the field of geography.

UNITED NATIONS CONFERENCE ON ENVIRONMENT AND DEVELOPMENT

The United Nations (UN) Conference on Environment and Development was convened between June 3 and 14, 1992, in Rio de Janeiro, Brazil, 20 years after the first global environmental conference in Stockholm. The primary focus of the Rio conference was to reconceptualize the global development agenda to include the sustainable use of natural resources. World leaders attempted to ameliorate the world's most pressing environmental issues by agreeing on a comprehensive strategy. This strategy aimed to meet current socio-environmental needs while ensuring a healthy and viable world for future generations. The Rio Summit boasted unparalleled representations from 172 governments, including 108 heads of state, and the participation of 1,400 nongovernment organizations (NGOs).

The 1984 Brundtland Commission (named after the chair, Norwegian Prime Minister Gro Harlem Brundtland) laid the foundations of the

Rio Summit. The commission published a provocative and widely circulated document titled *Our Common Future*. Lauded by the international environmental community, it derogated the world's failure to achieve development goals sustainably and outlined visionary actions for reversing anticipated environmental catastrophes. This document helped propel international support among world leaders for the Rio Summit and generally outlined the topics for discussion.

The main plan of action developed and adopted by the 178 governments at the Rio Summit is known as Agenda 21. It is a comprehensive blueprint for global, national, and local actions by UN organizations, governments, and major environment and development stakeholders. Ten years later, the World Summit on Sustainable Development (WSSD), held in Johannesburg, attempted to affirm UN commitments to the "full implementation" of Agenda 21, alongside the achievement of the Millennium Development Goals and other international agreements.

One of several other important achievements of the conference was agreement on the UN Framework Convention on Climate Change (FCCC), which aimed at stabilizing greenhouse gas concentrations at a level that would prevent dangerous interference in Earth's atmosphere. The FCCC later led to the Kyoto Protocol, a legally binding agreement among countries to reduce carbon emissions. Another key agreement adopted at Rio was the Convention on Biological Diversity. It established three principal goals: (1) conservation of biological diversity, (2) sustainable use of its components, and (3) fair and equitable sharing of the benefits from the use of genetic resources.

The Rio Summit was sharply criticized for its failure to include the regulation of businesses, financial institutions, and transnational corporations in Agenda 21 despite their central role as carbon emitters. Furthermore, several accords were left unmet after Rio, largely due to the United States' unwillingness to sign key treaties.

Presaging a growing civil society influence in UN covenants, 18,000 representatives attended a parallel summit specifically for NGO participants (a number that has swelled at consecutive UN summits). However, civil representation remained

geographically unbalanced, and civil society organizations remained ancillary collaborators to states and largely remained distant from the central politics shaping Agenda 21.

UNITED NATIONS ENVIRONMENTAL SUMMITS

The United Nations (UN) has laid the foundation for heightened global environmental awareness since the 1970s. A central approach to address these wide-ranging issues, and bring them to the forefront of the international agenda, is through high-level environmental conferences of national leaders. These summits have provided space for critical dialogue among world leaders, government representatives, and civil society. They have become the arena in which environmental objectives are set and plans of action written and adopted. Three major summits have convened since the 1970s.

The first of the global summits was held from June 5 to 15, 1972, in Stockholm, Sweden. It was the progenitor of the Rio Summit and the Johannesburg Summit and marked a historical turning point in terms of political and public recognition of environment and development issues at a global scale. The Stockholm Summit laid the basis

for international environmental cooperation and led to the creation of the United Nations Environment Programme and related global and regional environmental-monitoring networks. It also paved the way for civic engagement in the global arena. However, the actual number of civilian participants was low by contemporary standards, with fewer than 300 nongovernmental organizations (NGOs) attending.

Following Stockholm, the Brundtland Commission published a provocative and widely circulated document in 1984 titled *Our Common Future*. Lauded by the international community, it railed against the world's inability to achieve development goals sustainably and outlined visionary actions for preventing environmental catastrophes. It rallied international support among world leaders for another global environmental conference and generally outlined the topics for discussion.

The subsequent global conference was the 1992 United Nations Conference on Environment and Development (Earth Summit), held in Rio de Janeiro. By the time of the Rio Conference, the global environmental movement had gained momentum, and political will on behalf of governments to address environmental issues had grown substantially. Fourteen hundred NGOs were officially registered, and 18,000 representatives attended a parallel summit for NGOs. The main plan of action developed at the Rio Earth Summit is known as Agenda 21. It was adopted by 178 nations and is an all-inclusive outline of actions to be taken at all scales by UN organizations, governments, and key groups in all areas in which humans affect the environment.

The most recent of the UN global environmental summits was the World Summit on Sustainable Development (WSSD), held from August 26 to September 4, 2002, in Johannesburg, South Africa. Its main objective was to reinforce an intergovernmental commitment to sustainable development and natural resource use. It also took stock of developments since Rio. More than 20,000 participants from governments and NGOs, the private sector, and the scientific community participated. The large number of unmet accords inherited from the 1992 Rio Summit called for a novel approach to include civil society in global agreements and action plans:

the UN Stakeholder Forum Implementation Conference (IC). The IC was designed to mobilize stakeholder participation and facilitate the implementation of commitments established in Rio as embodied in Agenda 21.

While the UN summits have received increasing attendance and media recognition, concrete results have consistently fallen short of international agreements. Consistent summit shortcomings, leading to a sense of “summit fatigue,” shifting geopolitical coalitions, and struggling financial markets, will continue to challenge the accomplishment of summit accords.

UNITED NATIONS ENVIRONMENT PROGRAMME (UNEP)

The United Nations (UN) Environment Programme (UNEP) was created by UN General Assembly resolution 2997 (XXVII) on December 15, 1972, to act as the global and regional voice

for environmental policy within the UN system. This action followed the recommendation of the June 1972 UN Conference on the Human Environment, held in Stockholm, Sweden. The UNEP Secretariat was established in Nairobi, Kenya, and is headed by an executive director, who also serves as UN Under-Secretary-General. The executive directors included Maurice Strong (1973–1975), Mostafa Tolba (1975–1992), Elizabeth Dowdeswell (1993–1998), Klaus Toepfer (1998–2006), and, most recently, Achim Steiner (2006–present). The UNEP is funded by trust funds and funds allocated by the UN regular budget, by special earmarks, and by a voluntary Environment Fund. The largest contributors to the Environment Fund are the United Kingdom, Germany, the United States, and the Netherlands. There is a professional staff of around 500 working at the UNEP and a total of almost 1,000 employees. Several of the professional staff members are nationals from the United Kingdom, the United States, Germany, France, the Netherlands, Canada, and Japan, as well as Kenya. In addition to its Nairobi headquarters, the UNEP has regional offices in Washington, D.C., New York, Mexico City, Brasilia, Geneva, Brussels, Vienna, Moscow, Bangkok, Beijing, Cairo, Addis Ababa, and Manama (Bahrain). There are several additional liaison offices, division offices, and outposted offices around the world.

The UNEP's mandate is to coordinate the development of environmental policy consensus by keeping the global environment under review and bringing emerging environmental issues to the attention of governments and the international community for action. Its mission and objectives have been strengthened by several actions taken since the early 1990s. These include Agenda 21, adopted by the 1992 UN Conference on Environment and Development; the 1997 Nairobi Declaration on the Role and Mandate of the UNEP; the 2000 Malmo Ministerial Declaration and the UN Millennium Declaration; and the recommendations related to international environmental governance approved by the 2002 World Summit on Sustainable Development and the 2005 World Summit of the UN. The UNEP has five priority work areas: (1) environmental assessment and early warning, (2) development and implementation

of policy instruments, (3) enhanced coordination with environmental conventions (treaties), (4) technology and knowledge transfer, and (5) special support for Africa.

The UNEP is also one of three implementing agencies of the Global Environment Facility (GEF), along with the UN Development Programme and the World Bank. The GEF was set up to assist developing countries and those with economies in transition to pay for the incremental costs of measures and technologies designed to achieve global environmental benefits in six areas: (1) climate change, (2) ozone layer protection, (3) biological diversity, (4) international waters, (5) land degradation, and (6) persistent organic pollutants. This program, based in Washington, D.C., has provided more than \$7.5 billion in grants from donor countries for more than 2,000 projects in more than 165 countries since 1991 and has leveraged more than \$30 billion in cofinancing. It is also the financing mechanism for a few of the environmental conventions that are listed below.

The UNEP hosts several environmental convention secretariats, most of which are located outside Kenya. Among these are the Ozone Secretariat and the Montreal Protocol's Multilateral Fund; the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES); the Convention on Biological Diversity; the Convention on the Conservation of Migratory Species; the Basel Convention on the Transboundary Movement of Hazardous Wastes; the Rotterdam Convention on Prior Informed Consent (for international trade in banned or severely restricted chemical products); the Stockholm Convention on Persistent Organic Pollutants; and six Regional Seas Conventions and Action Plans. It also established the Intergovernmental Panel on Climate Change (IPCC), along with the World Meteorological Organization (another UN agency based in Geneva). The IPCC publishes special reports on topics relevant to the implementation of the UN Framework Convention on Climate Change. In 2007, the IPCC won the Nobel Peace Prize, which was shared with the former U.S. Vice President Al Gore Jr., for its work over the past two decades to build up and disseminate greater knowledge about anthropogenic climate change and to lay the foundations for the measures that

are needed to counteract such change. The UNEP first called for the negotiation of a climate change convention in 1985, which led to international agreements in 1992 and 1997.

Important accomplishments of the UNEP have been achieved in six areas. First, and most fundamental, are stronger international arrangements to enhance global environmental protection and security. Second, it has conducted periodic assessments and made forecasts to support decision making and international consensus on the main environmental risks and the responses to them. Third, it has provided support for more effective national and international responses to environmental risks, including policy advice to governments, multilateral organizations, and others to strengthen environmental protection and incorporate environmental considerations into the sustainable development process. Fourth, it has enabled a more effective coordination of environmental affairs within the UN system. Fifth, it has promoted greater awareness and institutional capacity for environmental management among governments, the private sector, and civil society. Last, the UNEP has promoted better understanding of the connection between the natural environment and human security, poverty eradication, and prevention and mitigation of natural disasters.

UNITED STATES CENSUS BUREAU

The Census Bureau is an agency of the U.S. federal government that produces a wide variety of statistical information for the public and private sectors. It has done so since the first federal census of population in 1790, in accordance with the provision in Article I of the Constitution that an “actual Enumeration shall be made within three years after the first Meeting of the Congress of the United States, and within every subsequent Term of ten years, in such Manner as they shall by Law direct.” This constitutional requirement has served as the basis for conducting a census of population at 10-year intervals ever since. In response to increased governmental and private sector demands for statistical information, the Census Bureau has become the federal government’s largest statistical agency and now produces many statistical series in addition to those derived from decennial censuses.

Regulations governing the collection of statistics by the Census Bureau, formally codified in the U.S. Code, Title 13, Census, require that statistical information remain confidential, meaning that the identity of individuals, households, or organizations that have provided information must not be revealed to any user. Important consequences for the geographic presentation of statistics derive from these regulations, particularly when the capabilities of modern geographic information systems (GIS) are taken into consideration. Data confidentiality safeguards often result in the loss of place-specific geographic detail; nonetheless, statistical information from the Census Bureau provides one of the primary empirical bases for understanding the nation’s human geographies, especially with regard to settlement, the characteristics of residents, and a wide range of economic topics.

A variety of geographic requirements are associated with each phase of collecting, processing, and presenting statistics. In the data collection phase, generally referred to as enumeration, one must locate and then obtain information from a person, household, business firm, or other unit of observation at a specific location, usually a street address. In the processing phase, geographic

The U.S. Census Bureau began updating its address list of the nation's approximately 130 million housing units in spring 2009. Census workers used confidential and secure GPS-equipped handheld computers to verify, add, and delete addresses. An accurate address list ensures that every household receives a census questionnaire in 2010.

Source: U.S. Census Bureau, Public Information Office (PIO).

identifiers are added to responses obtained in the collection phase that will be used to report the tabulated statistics. These requirements have remained essentially unchanged since the first census of 1790, but the manner in which they are operationalized has altered radically since then. The transformation of the nation from 4 million residents situated along the Atlantic Seaboard in 1790 to 305 million residents spread over a continent-scale country of 3.5 million mi.² (square miles) today has dramatically increased the geographic operational demands. Changing societal demands have brought about increased types of

statistical information, with more thematic type-of-area identifiers, for ever more specific locales. Still more dramatic, in terms of their impacts on geographic operations within the Census Bureau, are the technological transformations wrought by modern high-speed computers and the electronic processing of information during the latter 20th and early 21st centuries.

Geographic operations in the data collection stage have always included the necessity for producing innumerable local-area maps for in-the-field data collection. In the data-processing stage, enumeration areas—the basic spatial unit for

internal geographic operations—are created. They enable all subsequent spatial bookkeeping operations to occur. From the census of 1790 through 1870, the administrative districts of federal marshals served this purpose. With the 1880 census, Henry Gannett (1846–1914), the bureau's first professional geographer, established a geography program to produce field maps and enumeration areas that took into account both the physical features of the environment and the existing patterns of human settlement. These enumeration areas were then aggregated into geographic units for tabulating statistics. By the 2000 census, the number of these enumeration areas—the basic spatial units from which all geographic units for tabulating statistics are formed—had increased to 8 million.

Geographic operations for acquiring and processing responses always present formidable challenges in terms of maintaining the accuracy of place-specific geographic information associated with each response. Prior to high-speed computers, the Census Bureau produced detailed local-area maps from the best available sources, including local governments and topographic quadrangles, for such operations—a series of exceedingly tedious paper-based tasks. Beginning with the 1970 census, detailed geographic information was digitized to create reference maps to display geographic tabulation units in the Metropolitan Map Series, which covered 100,000 mi.² of the most intensively settled portions of the country. With the 1990 census, the Census Bureau introduced the TIGER® (Topologically Integrated Geographic Encoding and Referencing) database for managing its internal geographic operations and for creating reference maps that display the geographic units in which statistics are tabulated. This GIS has served as the basis of geographic operations of the Census Bureau ever since.

The historic evolution of geographic units that have served to report statistical information mirrors American society's increased expectations for data, which demand an ever-increasing variety of units with ever-greater geographic specificity. In 1790, the states themselves were the only formal geographic units required for reporting statistics, as the census was conducted explicitly to allocate seats in the U.S. House of Representatives and apportion the Revolutionary War debt

among the states. Since then, the number of geographic units provided by the Census Bureau for presenting statistics has increased dramatically, coming to include, among many others, various subnational regionalizations, units representing residential settings as small as city blocks (with at least 300 residents), units representing forms of settlement that range from urban and rural locales to metropolitan areas, and units that represent school districts and voting districts for state legislatures and the U.S. Congress. Today, users can create their own customized geographic units of analysis and have statistics tabulated online in real time via the Internet.

The Census Bureau has collected statistics, which were then made publicly available, from the initial decade of the federal government's existence. Today, the topics covered by this agency's statistics range from geographical mobility, foreign trade, and housing to hundreds of other topics. Frequency of issuance ranges from monthly to once per decade. The operational challenges faced by the Census Bureau to produce national-scale statistical data sets have resulted in countless innovations in geographic operations and in the tabular and the geographic/cartographic representation of statistics. Once instituted by the Census Bureau, these innovations have readily crossed over into the private and public sectors outside the federal government. They not only underlie the statistical base of knowledge provided by the federal government but also enable users of Census Bureau products to statistically analyze the processes that transform the nation's human geographies and how they relate to its physical environment.

UNITED STATES GEOLOGICAL SURVEY (USGS)

The United States Geological Survey (USGS) is a nonregulatory scientific research agency housed in the U.S. Department of the Interior employing scientists in five scientific disciplines—geology, hydrology, geography, biology, and geospatial information science—at more than 400 U.S. locations. USGS scientists provide decision makers with timely and relevant information on the nation's landscape, natural resources, and hazards. The USGS is the country's largest civilian mapping agency, providing online access to base data, map products, and geospatial Web services derived from satellite imagery, aerial photographs, and the 7.5-min. (minute) topographic maps of the United States.

The USGS was established by Congress on March 3, 1879. John Wesley Powell, its director from 1881 to 1894, initiated a plan for the topographic mapping of the entire United States. USGS

scientists contributed to the war efforts during World Wars I and II, trained the astronauts who landed on the moon in 1969 in geology, and helped launch the first civilian Earth-observing satellite in 1972, which evolved into the Landsat program that provides a continuous historical record of medium-resolution satellite imagery to the public.

USGS geologists study the causes and effects of geologic hazards such as earthquakes, volcanoes, and landslides; map the basic geology of the United States; investigate coastal change; provide assessments of energy and mineral resources; and contribute to an understanding of global climate change.

USGS hydrologists pioneered techniques for gauging the discharge in rivers and streams and modeling the flow of complex groundwater systems. USGS hydrologists provide information to minimize loss of life and property from water-related hazards such as floods, to manage groundwater and surface water resources, and to protect water quality.

USGS survey crew measuring mudflow damage, Upper Muddy River, with Mount St. Helens and the May 18, 1980, mudflow in the background. Skamania County, Washington, October 24, 1980.

Source: U.S. Geological Survey/Photo by Lyn Topinka.

USGS geographers and cartographers developed topographic mapping techniques using aerial photography during the 1930s, and they led the revolution in automated cartography and geographic information systems in the 1970s and 1980s. The 7.5-min. topographic map series of 55,000 quadrangles covering the United States was completed in 1992, and geographic data from these maps are the basis for *The National Map*, which provides online access to data from the USGS and its partners in federal, state, and local governments. Researchers in geography study the causes and consequences of land use and land cover change and hazard vulnerability, and they provide land use and land cover data through the Multi-Resolution Land Characteristics Consortium.

Biologists in the USGS provide scientific understanding and technologies to support the management and conservation of the nation's biological resources. Biologists study ecosystems, contaminants, aquatic resources, genetics, and endangered and invasive species. The USGS has developed the National Biological Information Infrastructure, a collaborative online system providing access to data and information on the nation's biological resources.

UNIVERSITY CONSORTIUM FOR GEOGRAPHIC INFORMATION SCIENCE

The University Consortium for Geographic Information Science (UCGIS) is an organization of universities and colleges, federal agencies, industry partners, and international affiliates whose purpose is to foster research and education in the field of Geographic Information Science (GIScience). UCGIS was founded in the early 1990s based on the recognition that a diverse and broad-based organization was needed to sustain growth in GIScience within the United States.

As described on the UCGIS Web site, the UCGIS mission and its associated goals are organized in three main thrusts:

Unify:

1. Provide ongoing research priorities for advancing theory and methods in GIScience.
2. Assess the current and potential contributions of GIScience to national scientific and public policy issues.

Facilitate:

1. Expand and strengthen GIScience education at all levels.
2. Provide the organizational infrastructure to foster collaborative interdisciplinary research in GIScience.

Benefit Society:

1. Promote the ethical use of and access to geographic information.
2. Foster GIScience and analysis in support of national needs.

Governance of UCGIS is conducted by an executive committee (made up of the president, the president elect, the past president, and the executive director) and a board of directors. The activities of the UCGIS are performed by the chairs of committees (research, education, policy and legislation, communications, and membership), who organize the work of the delegates. Delegates from the UCGIS 75-plus institutional members are scholars representing disciplines, including

cartography, cognitive science, computer science, engineering and land surveying, environmental sciences, geodesy, geography, landscape architecture, law and public policy, remote sensing and photogrammetry, and statistics. Each year, delegates and partners participate in a summer assembly and a winter meeting to coordinate research and education activities of national need.

Special workshops create significant products to advance GIScience research and/or education. Recent UCGIS products include the following:

- A GIScience research agenda developed from convening a 10-year diverse representation of delegates (McMaster & Usery, 2005)
- A monograph describing a GIScience and technology body of knowledge for education and research (DiBiase et al., 2007)
- A research agenda (Yuan & Stewart Hornsby, 2007)
- A research monograph (Stewart Hornsby & Yuan, 2008) about the topic of geographic dynamics

Each year, UCGIS conducts a search for a published research contribution that is worthy of national recognition and for an educator who has made outstanding contributions to GIScience education worthy of national recognition.

Current information about UCGIS activities can be found on the organization's Web site at www.ucgis.org.

UNSUPERVISED CLASSIFICATION

Unsupervised classification is one of the two basic approaches to digital image classification with the goal of producing land cover maps from remotely sensed data. The other is supervised classification. Unsupervised algorithms evaluate the spectral properties of image pixels and segregate them into naturally occurring statistical groups with little or no guidance from the analyst. The underlying assumption is that a remotely sensed landscape comprises a mosaic of land cover classes, each of which is relatively uniform in terms of spectral pattern. Following image classification, a significant challenge for the analyst is to apply meaningful land cover labels to the spectral classes identified. This entry summarizes the unsupervised classification logic, briefly examines two commonly used algorithms, and discusses the primary advantage and disadvantage of the approach.

Unsupervised classifiers are based on the multi-spectral data space location of spectral class means, the measurement of distance between class means and individual pixel locations, and the establishment of boundaries delineating the individuality of spectral classes. The amount of analyst-supplied input at the onset of the unsupervised classification varies by algorithm. In general, though, the algorithms work by assigning a number of image pixels, either systematically or at random, as initial class means. The distance between individual image pixel locations and the class means is calculated, and pixels are assigned to the nearest class mean. Once the entire image has been evaluated, new class means are calculated based on the addition of pixels to the initial mean value. The process then repeats, or iterates,

until there is a statistically insignificant change in the location of class means or in the number of pixels that switch class membership or until a maximum number of iterations is reached.

The two most commonly used unsupervised classification algorithms are K-means and the Iterative Self-Organizing Data Analysis Technique, or ISODATA. Both are iterative processes that, in general, operate as described above. K-means, however, requires the analyst to specify a fixed number of desired classes and then minimizes the within-class variability by optimizing the sum-of-squares error between individual class means and member pixels. ISODATA is more flexible, in that spectral classes can be merged or split. Classes are merged when two or more class means are located in close proximity. A class is split when its standard deviation exceeds a threshold value.

Relative to supervised approaches, a primary advantage of unsupervised classification is that the potential for human error is reduced. That is because there is less input required from the analyst and because of the high likelihood that each unique spectral class in an image will be identified. Unlike supervised classification, no prior knowledge of the study area is required to initiate an unsupervised process. However, detailed knowledge of the study area is needed to accurately label the resultant spectral classes. The primary disadvantage is that matching spectral classes to the desired set of land cover classes can be difficult.

UNWIN, DAVID (1943–)

Born in Chesterfield, Derbyshire, United Kingdom, David J. Unwin was among the first generation of students trained in quantitative geography. With the recognition of geographical information science (GIScience) as a research domain, he became a leading member of that community, having published his landmark text *Introductory Spatial Analysis*, which formed the precursor for *Geographic Information Analysis*, which he coauthored with David O'Sullivan.

Unwin graduated in geography from University College London in 1965 and received his MPhil degree in 1970. By then, he was a lecturer of geography at the University College of Wales at Aberystwyth. In 1973, he moved to the University of Leicester, where he worked until he moved to Birkbeck College, London, in 1992 as professor of geography. He was pro-vice master of the college (2000–2002), before moving to serve as director for learning programmes at UK eUniversities Worldwide Limited. He retired in 2004.

Two principal themes characterized Unwin's research: (1) teaching and (2) computing/geographical information. He was concerned with improving the quality of teaching in British higher education, especially computer-assisted education, and he served on various geography curriculum committees in both British schools (A levels) and universities. His contributions to research on teaching are also illustrated by his work on the *Journal of Geography in Higher Education*; he was a member of its founding editorial board from 1977 to 1986, and he served as coeditor from 1986 to 1989.

Unwin's research in the area of computing led to the writing of key books, titled *Computing for Geographers* in 1976 and *Computer Programming for Geographers*, in 1985 and leadership of a number of research grants for computer-based thematic mapping. In GIScience, his principal research contributions have been in cross-area estimation (with Mitchel Langford, University of Glamorgan) and in visualization and virtual reality, which led to coedited books.

The two interests came together in a string of grants such as the Leicester Image Processing

Suite, Computers in Teaching Initiative Centre for Geography (codirected with David Maguire), Visualisation for the Social Sciences (a Leicester-Birkbeck collaboration), and the Virtual Field Course Project (a Leicester-Birkbeck collaboration). Outside geography, his administrative responsibilities at Birkbeck and UK eUniversities were related to both teaching and technology.

Unwin's most notable service to the research community was for the Quantitative Methods Study Group of the Institute of British Geographers as the secretary/treasurer (1974–1976), as chair (1976–1979), and as editor of the CATMOG series (Concepts and Techniques of Modern Geography, 1979–1982). He also participated in establishing the first European Colloquium on Theoretical and Quantitative Geography in 1978.

Unwin's MPhil research was in climatology, and he maintained interest in this area throughout his career. Merging this with a lifelong interest in fell running and mountaineering, in 1978, Unwin authored *Mountain Weather for Climbers*.

URBAN AND REGIONAL DEVELOPMENT

Students of urban and regional development consider the social, economic, and political forces that shape, and are shaped by, the physical and social landscapes of metropolitan areas. Urban and regional development is a multidisciplinary subject of study that draws interest from scholars affiliated with a broad range of social and physical sciences, including planning, sociology, geography, political science, anthropology, and health and environmental sciences. The multidisciplinary nature of urban and regional development should not be surprising given the significance of the city, and more recently the concept of the region, in each of these disciplines. Placing a boundary around the term *urban and regional development* is, consequently, a difficult task. Indeed, given the disciplinary intersections inherent in urban and regional development, any effort at delimiting the literature would unfortunately result in omissions that some may find problematic. Nevertheless, what follows is an attempt to be as inclusive as possible concerning urban and regional development and its theoretical evolution.

Origins of Urban and Regional Development

Like most academic concepts, the origins of urban and regional development can be traced to broader intellectual pursuits combined with changes in wider economic, cultural, and political conditions. In geography, students of urban and regional development emerged from the sub-disciplines of urban and economic geography. Early geographical models of urban development were often econometric. Walter Christaller's central place theory, for example, focused on the placing and spacing of urban settlements by examining the geographical draw of hierarchies of economic goods that, in turn, produced hierarchies of settlements spaced equidistant from each other by virtue of the mix of goods and services found in them. Brian Berry used central place theory to understand distributions of urban settlements and economic activities in the Midwest of the United States.

Early contributions from sociology include Ernest Burgess's studies of Chicago, in which he viewed the city as a laboratory for the study of urban form and urban social problems. Cities were seen as organic, expanding and changing in social and physical form in a process similar to the succession of plant life. The structure of urban form and growth appeared to be in concentric zones, with the central business district (CBD) at the center and surrounded by a transition from the CBD to more residential areas, which in turn were structured into concentric zones by levels of affluence. The mobility of citizens, measured in journey-to-work commutes, use of telephones, and land values at strategic locations (and change in the number and spatiality of strategic locations), is couched in terms of a city's "metabolism" and reflects the "vitality" and "health" of a city's economic and social life. Additionally, "disorganization" of urban life in the form of vice, poverty, concentrations of minority populations, and disinvestment in the built environment is attributed to the "excess" of actual population growth over natural increase (i.e., immigration). Disorganization along with the demand for labor are seen as natural to urban life and appear to act as "stimulants" for the mobility of citizens, creating pressures for urban expansion and succession of land uses.

Anthropological contributions to urban and regional development focus on the cultural and social life of cities. Urban cultures and subcultures are examined within the context of specific groups navigating and shaping the built environment through everyday life practices, providing "the city" with vibrancy—different smells, ethnic cuisines, cultural and religious activities, markets, tempo, entertainment, and family and social gatherings. Particular groups, whether ethnic enclaves in specific neighborhoods or organizational units such as corporations and civic institutions, are examined to identify the cultural practices that collectively provide individual cities with their unique sense of place.

Planning and health and environmental science concerns arose largely in response to the rapid urban growth associated with industrialization in the 19th century. The need to regulate and spatially segregate various kinds of urban development and provide for infrastructural

requirements arose from the rapid and haphazard development of thickly settled tenement housing in cities such as New York in the 1800s. Health and environment concerns drove the creation of infrastructure such as sewage, water supply, and ordinances for the designing and spacing of buildings to allow sunlight to penetrate densely constructed urban areas. The need for such planning became evident after the outbreaks of diseases such as cholera, typhoid, yellow fever, and dysentery in the crowded and unsanitary quarters of industrializing cities such as New York and London.

Following World War II, planning practices shifted toward accommodating the fast-growing suburban populations. Planned private suburban communities such as the Levittowns of New York, New Jersey, and Pennsylvania—along with others scattered about the United States—were aimed at accommodating the high demand for housing for a burgeoning middle class in the postwar United States. In the latter part of the 20th century, public planning became more prevalent in the United States as environmental concerns emerged in the 1970s and 1980s against the backdrop of increasing pollution and other negative externalities associated with rampant leapfrog suburban development. In Europe, where national governments are generally more centralized than in the United States, planning practices largely focused on decreasing densities around public transportation nodes and expanding the public transportation infrastructure. It should be evident here that the United States and Europe diverged in developing their respective transportation infrastructures. The United States focused primarily on constructing and maintaining its interstate highway system to accommodate the growth of privately owned automobiles. Suburbanization, including leapfrog development, generally follows the contours of the interstate highway system. Europe's preindustrial and pre-automobile cities with narrow streets and high densities were not easily malleable to the kinds of urban structural change required to accommodate limited-access highway systems. Consequently, the major focus in Europe was largely on public transportation such as high-speed trains, subway systems, and light rail systems, which are less intrusive on the built environment. The planning professions in the

United States and Europe thus reflect the social and cultural implications associated with these differing transportation infrastructures.

Urban Governance

The 1950s and 1960s saw the publication of a series of works that broadened the scope of urban and regional development to include urban governance. The publication of Floyd Hunter's book *Community Power Structure* in 1953—a Marxist analysis of a “Regional City’s” (largely understood to represent the city of Atlanta) close ties between the city’s business class and the city government—launched a new theoretical framework for studies of urban and regional development. Rather than viewing the social and built environment as “natural” or organic, the new focus was on how class dynamics (re)produces the social and economic landscape in modern capitalist cities. The business community, for example, was recognized as pivotal in a city’s social and political structure. The leaders of the business community are seen as more than representatives of their particular company or industry; rather, they are seen as representatives of a *class* of capitalists who police and act on behalf of class interests in addition to the interests of their particular businesses. This is done through the establishment of business policy organizations in which local firms offer their expertise and resources to local government officials to help shape urban policies. In addition, business leaders financially back pro-business candidates for office and tend to head local community foundations, arts councils, and other eleemosynary organizations to merge the resources they command, including social and political networks, for the purpose of fund-raising and/or mobilizing the kinds of support that such organizations require to function.

The publication of C. Wright Mills’s *The Power Elite* in 1956 and G. William Domhoff’s *Who Rules America?* in 1967 broadened the scope of the community power structure literature beyond the confines of “the city” to include national governance. Much of this broadened literature considers the socialization mechanisms of preparatory schools, elite universities, and exclusive social clubs as components of a social structure organized for the inculcation and maintenance

of class awareness for new generations of business and social leaders at the national scale.

The political scientist Robert Dahl’s *Who Governs?* (published in 1961) refocused on the urban scale and challenged the burgeoning school of community power structure. Dahl’s book was a long-term study of the governance of the city of New Haven in Connecticut. Rather than finding a small class of business or social elites who overly influence urban policy making in New Haven, Dahl described a tumultuous process of negotiations and quid pro quos among myriad social and business interests. Additionally, Dahl found a very dynamic set of actors whose composition changes dramatically with the rise of the industrial revolution, rapid immigration, and the subsequent changes in urban form and structure. The process of urban governance over time that Dahl describes is one of transition from an era of elite leadership in the early days of British colonialism and then U.S. independence to a steady rise of interest groups that increasingly diminishes the power of any one group to overly influence urban government. In other words, urban governments must be responsive to a widening array of interests. The result, then, is a process of municipal governance and urban development that appears to be chaotic but in actuality represents “a miracle of democracy” in the sense that political influence is effectively diluted by the need for urban governments to be responsive to a widening, pluralistic range of voters.

The work of Robert Dahl effectively launched what in political science is known as the “pluralist school,” which remains a powerful framework for contemporary studies. Indeed, throughout the 1970s and 1980s, urban scholars generally worked within the framework of either the “elite school” of community power structure or the “pluralist school,” with little overlap between the two. The two models are largely separated by epistemology—that is, they differed in their expectations of what can be researched. Pluralists, for example, take a “decisional” approach and analyze actual decisions (e.g., legislation and the decision-making processes behind them) regarding urban policies. They generally conclude that political influence is decentralized but imbalanced among a range of competing interests. Meanwhile, anything beyond concrete decision

making is, according to the pluralists, beyond the confines of scientific inquiry. Elite theorists, on the other hand, assume that the desires of local elites (usually business elites) guide the political process behind the scenes and limit the scope of the political process to only those issues that are comparatively innocuous to local elites. Methodological approaches in the elite theory tradition—popularized by Floyd Hunter—involve reputational analyses in which decision makers are interviewed to gauge their assessment of the involvement of people who, by the nature of their perceived high social or economic status, possess the potential to tacitly influence the decision-making process. The split between the elite theorists and the pluralists continued into the mid 1970s, until Harvey Molotch's seminal article on urban growth machines, published in 1976, changed the terms of the debate.

Growth Machine, Urban Regimes, and Regulation Theory

The growth machine hypothesis broadens the scope of urban politics in urban and regional development to include more than political decision making. The sociologist Harvey Molotch's growth machine hypothesis was laid out in greater detail with the publication of *Urban Fortunes* in 1987, a book that he coauthored with John Logan. The growth machine hypothesis conceptualizes cities as battlegrounds of competing interests between what they refer to as "rentiers"—a class of people who, as property owners, earn their living from rent—and "users." Elites are recast as those with a variety of interests favoring economic growth: They include, for example, property owners who seek to maximize the "exchange" values of their properties; newspaper executives who seek to increase readership, which, in turn, increases the demand for advertisements; city government officials who would prefer to see tax revenues increase; local businesses and utility companies desiring more industrial customers; universities seeking increased enrollments; unions seeking to increase the pool of local jobs for their constituents (and increase membership); and the arts, sports franchises, and philanthropy institutions, seeking increased audiences and contributions. These disparate groups

of interests ostensibly act as a unified business class that collectively influences urban and regional political decision making by virtue of the myriad financial and social resources at their command.

With growth machines at the heart of political coalitions across a range of U.S. cities, what emerges is a "battle of the growth machines"—that is, competition among cities and places for various forms of inward investment. The geographer David Harvey, for example, observed that city governments had largely transformed during the 1980s from concerning themselves primarily with effective and efficient municipal service provision to, instead, participating as agents of speculative investment making in local land uses with the aim of laying the groundwork for private inward investments. Cities by and large were faced with broader changes in global economic structure with the emergence of data processing and communications technologies in the developed world, which, in turn, intensified global competition and prompted a dramatic shift of the manufacturing sector to the emerging economies. The economies of the developed world, meanwhile, largely transformed into flexible high-technology production and services. In short, as the geographer Kevin Cox details, "capital" has become increasingly mobile across space as a consequence of globalization, prompting a "new urban politics" in which localities must respond by becoming more "entrepreneurial." This entails investing public revenues into speculative ventures, such as the provision of location and tax incentives to firms that would locate new production or other facilities nearby or to existing locally based firms to prevent them from relocating out of a particular jurisdiction. Furthermore, speculative ventures include the building of new stadiums, convention centers, and arts facilities and developing restaurant-and-bar districts or other "places of consumption" that aim to be a draw for the "creative-class" workers of the new high-technology manufacturing and service-based economy.

The publication of the political scientist Clarence Stone's book *Regime Politics* in 1989 brought together the elite and pluralist schools more so than the growth machine concept. Stone's book was another long-term study of the

city of Atlanta, Georgia, largely covering the years since the publication of Hunter's work in 1953. The urban regime concept's breakthrough in bridging the gap between community power structure and pluralism lies in its situating of political leaders within the constraints of the democratic process; that is, regime theory recognizes that urban politicians must be responsive to myriad interests as the pluralists contend. At the same time, however, regime theory also recognizes that business interests appear to wield more influence than others over the formulation of urban policies. In capitalism, business leaders—through no action of their own—are seen as possessing “systemic power” by virtue of their private ownership over the productive assets of society. Particularly in the United States, urban governments are reliant on their business communities for fiscal solvency because of the vital resources they command—namely, jobs and capital. Municipal governments, therefore, have traditionally been more responsive to the long-term needs of business community leaders over the needs of other constituents and have actively engaged with business leaders through informal networks to develop various political platforms. In short, *governance* is a more apt description of urban management and development given that urban governments alone lack the resources required to effectively develop and implement policies. Therefore, political leaders must reach out to the broader community—typically the business community—to mobilize the necessary resources for effective governance.

The regime concept proved to be problematic when applied to British or other European cities, where governments are more centralized and generally less dependent on local resources for effective governance. In Britain, regulation theory found more fertile academic ground than the concept of urban regimes. Led by the geographer Bob Jessop, regulationists explore the modes of “social regulation” and their roles in urban and regional development. Social relations—labor markets, capitalist competition, consumption, social movements, and so on—are seen as being mediated through governmental, social, and civic institutions at varying and interlocking scales of interaction. How these relations are mediated and directed help shape and direct the forms that

urban and regional development takes. Agglomeration economies, deindustrialization, the rise of “cultural” economies, and the like are attributed to specific locally based arrangements of regulatory institutions and social relations. Ash Amin and Nigel Thrift have referred to these arrangements as “institutional thickness” and attribute a locality's capacity to secure inward investments and “embed” global forces of production in particular places as contingent on a locality's level of institutional thickness.

Regulation theory brought to the fore the issue of scale that was hitherto undeveloped and largely absent from studies of urban and regional development. The concept of institutional thickness is cognizant and inclusive of various institutions—governmental, economic, social, and otherwise—operating at a range of scales. The “region” as opposed to the “city” is seen as particularly important for harnessing and directing the powers of regulation and social interaction toward embedding global processes in particular places. Authors have drawn from the works of others in the broader discipline of economic geography, including the concept of the “city-region,” for a better framework for understanding institutional thickness across scales. Others have called for a new politics of the “region” as opposed to the “city” so that cities and regions are better equipped to respond to the changing scales of global production and exchange.

Conclusion and Future Directions

The multidisciplinary field of urban and regional development is a rich and dynamic field of study. Although much of the work has been presented somewhat in a linear fashion, it should be noted that the various approaches to urban and regional development outlined above continue to flourish both independently and with much cross-fertilization of concepts, insights, and methodologies. Each approach offers promising insights for future directions of inquiry.

One particularly promising approach to urban and regional development has emerged from the broader discipline of human geography. The attention to issues of scale as outlined above has permeated much of social inquiry in human geography and other social sciences. The concept

of scale as networks and the “return” of graph theory in broader social science, along with new software technologies created specifically for network analyses, offer interesting methods for isolating specific interests identified in models such as urban regime theory, regulation theory, and “institutional thickness” in urban and regional development. Recent work, for example, seeks to identify specific business interests that enjoy centrality in urban regime coalitions through social network analysis. Others demonstrate the utility of viewing previously “amorphous” concepts such as globalization as economic transactions mediated through specific social relations and networks across space, linking regions and localities to “global” capital. Social networks and relations take the form of potential suppliers and business partners bridging global capital with local or regional markets and of customers representing forward and backward linkages up and down the production chain. This new thrust of inquiry promises to situate urban and regional development amid specific social, economic, and political actors that, collectively, constitute “coalitions,” “institutional thickness,” and other structures of social relations. By teasing out specific actors from these broader social forms, new possibilities emerge, with implications for human agency, urban social movements, and political action.

URBAN AND REGIONAL PLANNING

Think of the things one sees in a city or region that everyone wishes were otherwise. They might have been otherwise if there had been careful planning in the past. The periodic confrontations over the building of new shopping centers, high-rise apartments, airports, landfills, and highways; the demolition of historic buildings; or the failure to conserve open space are a measure of the regard with which planning is held. In these contentious situations, the subject under debate is not the need for planning but rather the need for better planning, not *whether* but *how* it should be done.

Planning is a systematic process of thought and action intended to contribute to effective decision making for the welfare and integrity of communities and the sustainability of the natural environment. It involves forethought and the judicious or systematic use of scarce resources to attain a desired goal. The primary objective of planning is to make an informed decision. This entry reviews the history of planning, its development in the areas of both urban and regional planning, and the characteristics of the planning process itself.

History

Planning has been going on throughout history, and it is tempting to explain it away by merely stating that humans have a natural urge to plan; it is part of humans' organizational makeup. Historians and anthropologists have uncovered evidence of planning from the classical civilizations of Greece and Rome to the nation-states and mercantile empires of the 19th century; in America, from the Iroquois confederation to the Inca and Aztec empires in Mexico; in Africa, from the tribal empires of the Ashanti and Mali in West Africa to the Zulu Empire and the kingdom of Zimbabwe in Southern Africa; and in the East, from the early cultures of Japan and China to the Persian Empire. The roots of planning extend to the first emergence of structured societies at the dawn of human history. Indeed, the planning of common activities, in the sense of deliberate anticipation, and the development

of strategies for action are evident in all primitive human societies.

Planned cities were at the core of all great pre-classical civilizations. Evidence lies in the layout of early Roman and Greek cities and in the civilizations that developed in the Indus River valley. Greek cities were based on a grid system layout, and they included standard elements such as a temple complex or Acropolis, a marketplace or Agora, and a recreational complex made up of an amphitheater (for theater and performances) and a hippodrome (for sports events and chariot races). Such was the plan for the city of Miletus, which was planned by Hippodamus, the father of town planning, in 480 BC. In North America, early urban settlements were generally preplanned in Europe before the settlers set off for the New World. For instance, Savannah, Georgia, planned in 1733 by James Oglethorpe, was inspired by the layout of London's residential squares. Each square contained 40 residential lots laid out on a modified grid around a central square.

In addition to the traditional role of designing a city's physical form, planning expanded in the 19th century to include slum clearance, urban renewal, suburban development, transportation planning, urban growth management, and environmental planning. Today, planning has become so complex that it is useful to categorize it into three forms: (1) substantive planning, (2) contextual planning, and (3) spatial planning. Substantive planning refers to the functional areas of planning interest, and specific types include environmental planning, health planning, transportation planning, and physical or land use planning. Contextual planning refers to the context of planning, and specific examples include comprehensive planning, regulatory planning, policy planning, and strategic or long-range planning. Finally, spatial planning refers to the spatial aspect of planning, such as rural, urban, and regional planning.

Urban Planning

Urban planning is also referred to as city, town, or community planning. In Britain, the term *town planning* has been used since the late 19th century. "Community planning" entered the Canadian lexicon not long after World War II, when

the Community Planning Association of Canada was formed. In the United States, the comparable term is *city planning*, and it emerged shortly after 1900. However, in both Canada and the United States, “urban planning” has also become the accepted term since 1960. Urban planning is defined as a systematic process of identifying community goals and specific land use objectives, exploring and assessing the options available to the community, and choosing and implementing the best option. Its purposes are to fulfill the following:

1. Minimize or avoid an unsatisfactory state of affairs such as urban sprawl, traffic congestion, and environmental degradation
2. Protect the health, safety, and welfare of the urban society
3. Ensure efficient allocation of scarce public resources

Most of the urban planning activities involved reconciling private and public preferences to solve problems caused by growth and development. The planning profession has evolved over the past century.

Urban planning in the decades following World War II was concerned with how to accommodate vast population increases by providing housing, public utilities, parks, schools, and public transportation. Cities and towns in this era were often subject to epidemics of diseases and prone to extensive fire hazards. Their new populations needed adequate housing, water, and sewage systems. The 1960s began with major concerns over the physical deterioration in communities. Hence, urban renewal became the focus of planning efforts until the “bulldozer approach” used to achieve it was called into question by Jane Jacobs in her famous book *The Death and Life of a Great American City*. In the 1970s, urban planning concerns focused on the effects that large-scale projects such as airports, shopping centers, and apartment complexes might have on the existing community environments.

Another response to urban problems in the early 1960s was the emergence of a cadre of professionals who gradually codified their ideas and experience about solving urban planning problems. The urban planning profession emerged

during this period and has since generated a rich array of planning concepts, theories, and processes that continue to be drawn on heavily in contemporary planning practice. Modern planners have mastered the techniques for preparing plans and are able to involve a wide range of people in the planning process. Besides, today’s planners understand the legal foundations and techniques for plan implementation and are able to articulate planning issues to a wide range of audience.

Regional Planning

Few planning problems are confined within individual communities. The reasons stem from the interrelationships of various socioeconomic and natural processes in a community and the ways in which the effects of development are transmitted through space. For instance, the drainage of storm water from a subdivision located on a watercourse has the potential of causing pollution to areas downstream. Hence, it is often necessary to undertake planning for areas larger than a single community and large enough to encompass the major effects of a single development project. When large areas are distinguished by identifiable unifying characteristics, they are called “regions.” Regional planning is concerned with many different facets of the physical and human environment over large areas that may or may not have well-defined political boundaries. Regional planners attempt to visualize a better future for a region and recommend steps to achieving a desired vision.

One of the first planners to advocate the need for larger-area planning was Patrick Geddes. After observing a rapid spread of urban development in 19th-century Britain, Geddes coined the term *conurbation* to capture the interdependent nature of linked cities. He drew attention to the independence of all activities within a geographic unit such as a watershed to emphasize the need for regional planning. Ebenezer Howard also deserves credit for the emergence and development of regional planning. His publication titled *Garden Cities of Tomorrow* (1902) helped initiate the Garden City movement. The movement was not only concerned with planning single new towns but was also based on the concept of

organizing a territory around large cities to minimize sprawl and conserve natural resources far beyond the city.

The trend toward regional planning is buttressed by the following developments: (a) urban space has become a series of interconnected districts that stretch across a vast geographical area, (b) economic relationships exist between residents in towns and those in the country, and (c) there is a need to avoid wasteful duplication of planning efforts or facilities in several local jurisdictions. Regional planning recognizes the need to take a synoptic approach to areawide problems and the planning of each jurisdiction in coordination with adjoining areas. A successful example is the river-basin-planning activities of the Tennessee Valley Authority (TVA). The TVA is a regional planning authority that transcends the jurisdictions of seven states, including Virginia, Georgia, Mississippi, Kentucky, Virginia, North Carolina, and Alabama. In establishing the TVA in 1933, the U.S. Congress showed its awareness of a growing trend toward regional planning and an understanding that many of the problems of the Tennessee Valley could hardly be solved by individual states acting alone.

Regional planning is also done at a metropolitan level. Metropolitan regions often have a core city and hinterlands that have noticeable economic and social links. A typical metropolitan region in the United States contains multiple local governments—an average of 104 jurisdictions, which include (a) general-purpose governments in counties, municipalities, and townships and (b) special-purpose governments such as school districts, fire districts, and industrial districts. Regional planning minimizes duplication of public services and development efforts by forging partnerships with local governments as well as the business and nonprofit sectors. Given the autonomy accorded to local government units, regional planning blends their competing aims for development in the interest of all citizens of a metropolitan region. This requires special organizational arrangements, such as the Regional Council of Governments, Regional Planning Commissions, or the Metropolitan Planning Organization (MPO) in the United States. For instance, MPOs serve as the decision-making body for federally funded transportation projects

within a metropolitan area. They also prepare and maintain long-range transportation plans with input from the general public.

Process

A traditional planning process is used in urban and regional planning practice. The process begins with problem diagnosis or dissatisfaction with a status quo situation. Planners work with the general public to articulate a common goal or vision. Next, the vision or goal is refined into a set of objectives that are specific, quantifiable, and measurable. The objectives serve as milestones toward the desired goal. A study is undertaken to assemble facts and figures that enable planners to develop alternative courses of action consistent with the stated goal and objectives. The study may involve the survey, analysis, prediction, and projection of future needs or a future state of affairs. The best course of action is chosen, implemented, and monitored for consistency or unintended consequences. Public participation is essential at each stage of the planning process because it helps (a) incorporate public concerns and values in the planning process, (b) minimize opposition by developing a consensus among stakeholders, and (c) build credibility between planners and the general public. Overall, the traditional planning process is seen as a systematic, rational, and comprehensive decision-making tool.

URBAN ECOLOGY

Urban ecology has traditionally been considered a field of inquiry emphasizing ecological processes and organization under the conditions of industrial urbanization. There is a growing interest in interdisciplinary, urban theoretical and scholarly research among the natural, social, and planning sciences, especially within the context of rapid global urbanization, population concentration, and industrial and environmental change. As a field of academic inquiry, urban ecology reflects and embodies changes and transitions in both urban theory and ecological theory over the past half-century.

Early Developments

Early urban ecological exploration and explanation in the mid 20th century reflected contemporary ecological thinking and theory involving the supposed linearity and directionality of ecological change (or succession) and the relative stability, efficiency, and coherence of ecological structure and organization. To this end, early academic interest in the effects of urban industrial growth

on natural environments and ecological processes emphasized the degrading character of cities, with urban form and function critiqued and characterized as anathema to the form and function of “healthy” environmental systems. Industrial pollution, human waste, landscape fragmentation, and the growing and spatially concentrated demand for natural resources by industry and urban consumers were—and to a large degree still are—implicated in declines of air, water, and soil quality at local and regional scales, with broad environmental, social, and economic implications. Similarly, the replacement of native local and regional fauna and flora with nonnative, or invasive, species of plants and animals was implicated in the overall and generalized diminishment of urban landscapes, where local and regional biodiversities were being replaced by more homogeneous, weed-based ecological communities.

Because “nature” was, from this perspective, abolished by the city, then—by implication—its study, in the form of ecology, was antiurban, both in theory and in practice. The nonurban, or rural, remained the principal domain of “true” nature and, thus, of ecological inquiry throughout most of the 20th century. The implications for subsequent constructions of and distinctions between *urban* and *rural*—that is, the city (and urban society) as degrading and degraded and the hinterland (and rural society) as a more ecologically uncontaminated place—have been the topic of sustained critique and debate.

The Role of Human Ecology

By the late 20th century, urban ecology had emerged as a key object of explanation and academic inquiry among an interdisciplinary population of, principally, North American scholars. Equipped with a new set of ecological principles and concepts, and integrated theories of human-environment interaction, these *human ecologists*—ecologists, anthropologists, sociologists, and resource managers, many trained in rural or developing regions of the world—brought to the study of urban ecology a more sophisticated and nuanced appreciation of human-environment relationships in cities, whereby urban society and urban environments were understood as coregulated and codependent systems whose

interaction was nondeterministic, dialectical, and involving dynamics of feedback and change along multiple axes and gradients, from the purely physical to the socioeconomic. Anthropogenic environmental change, it was theorized, resulted in new sets of material and spatial conditions to which urban society responded and adjusted, which, in turn, resulted in further environmental change, future adjustments, and so forth.

This new systems approach of urban human ecology (not to be confused with the Chicago School of Human Ecology, developed in the 1920s, which focused on social and cultural relations within cities) replaced the ecological principles of balance, linearity, and stability (i.e., those concepts that fed accusations of environmental degradation) of earlier critiques with new models emphasizing the impacts of change, nonlinearity, and chaos on ecological structure, form, and function. The result was a new emphasis on the *humanized* urban ecosystem, one in which urban society was a fundamental organizational component and agent of nonnormative and nonlinear environmental change at various spatial and temporal scales. Urbanization, from this perspective, amounts to a form of environmental disturbance to which the natural system and, subsequently, human systems respond in dialectical fashion. This model of urban human ecology thus disposed of earlier nature-society, urban-rural dualisms to argue that cities are, in fact, fully functioning and viable ecosystems and that the politically charged “degradation” is better understood and explained as a form of systemic change to which urban societies respond and adapt. The 1997 emergence of the flagship journal *Urban Ecosystems* and the parallel development of the, traditionally nonurban, Long-Term Ecological Research (LTER) Project sites (funded by the U.S. National Science Foundation) in Baltimore, Maryland, and Phoenix, Arizona, signaled the legitimacy and success of this new, more interdisciplinary model of systems-based urban human ecological thinking and scholarship.

Urban Environmental Services

Parallel to the emergence of urban human ecology in the 1990s was a growing interest in the economics and social value of ecosystem services,

sometimes called environmental services. The services perspective argues that healthy urban ecological communities provide myriad unintentional benefits that justify environmental protection, management, and/or restoration. These services include the removal of pollutants and toxins from air (via photosynthetic activity and soil respiration) and water (via root uptake, soil filtration, and plant transpiration), soil stabilization (via root structure), and temperature regulation (via shade from trees and forests or heat absorption by urban water sources). On the one hand, scholarship in the area of ecosystem services argues that “healthy” and intact urban ecological systems, if protected and managed properly, have the capacity to absorb much of the effluent and wastes of industrial production and social consumption. This perspective calls attention to the—largely unaccounted for and unappreciated—economic benefits of healthy urban ecosystems that accrue at multiple scales, from the household to the municipality to the region. Urban ecological degradation, thus, does not simply represent a future expenditure (i.e., through technological investment, environmental remediation, restoration, or containment) but entails an opportunity cost of likely significant magnitude. On the other hand, the services perspective advances the argument that the benefits provided by “healthy” urban ecosystems fall under the category of quality-of-life indicators demanded by urban residents, whereby healthy ecosystems promote urban social and economic health and a healthy, happy, and productive urban citizenry.

To this end, insofar as they meet certain quality-of-life criteria and satisfy public demand, healthy urban ecosystems are said to help produce the conditions of economic development, including the attraction of tourists, jobs, and full-time residents. Borrowing principles that are reminiscent of Frederick Law Olmsted’s ideas a century ago, this language of urban sustainability and the sustainable city has its origins in the fields of urban landscape architecture and design. In doing so, and in recognizing and representing the city as the container of (potentially) viable and healthy ecosystems, the services perspective strongly refutes earlier arguments and perspectives that alluded to cities as a priori environmental abominations.

Critical Urban Ecology

Apolitical and ahistorical urban ecological thinking and analysis generally characterized both the human ecology and the ecosystem services perspectives of the late 20th century. A response to this has been a more critical inquiry into the structural underpinnings of urban ecological change, the unequal distribution of ecosystem services and their quality-of-life and economic benefits, and the unequal distribution of degraded urban ecological landscapes and their potential risks. This emerging critical urban ecology, or *urban political ecology*, is based largely in the discipline of geography and is a nascent, if growing, area of interest among, especially, urban theorists and scholars, rather than ecologists, per se. Closely allied with urban environmental justice, urban political ecology emphasizes the modern urban environment as a historical construct of industrial urbanism and fragmentation, one whose patterns and rights of access, use, distribution, and change are contested and (re)negotiated along myriad axes of political and economic power. A hybrid of Third World political ecology and critical urban theory, urban political ecology reframes urban human-environment relations as the product or a reflection of unequal social relations and seeks opportunities for urban ecological inclusion, the right to urban nature, and thus the right to the city.

URBAN ENVIRONMENTAL STUDIES

Urban environmental studies are emerging as an integrated science aiming to understand extended urban areas that include not only biological and physical features but also economic and social components. These studies improve our

understanding of urban climate, hydrology, ecosystems, and environmental conditions and help us gain critical knowledge of how human and natural environments have interacted to motivate past urban environmental changes. The crux of science in urban environmental studies concerns the fluxes of energy, water, and carbon, how these fluxes are related to one another, and how they have changed over space and time. A better understanding of these science questions contributes to building a conceptual framework for sustaining the urban environment and thus enhancing the quality of life of its residents. The complexity of urban environmental issues calls for a systematic approach by interdisciplinary teams. This introduction reviews most important concepts and research methods in urban landscape, climate, water, vegetation, and sustainability.

Urban Landscapes

Urban landscapes are typically a complex combination of buildings, roads, parking lots, sidewalks, garden, cemetery, soil, water, and so on. Each of the urban component surfaces exhibits unique radiative, thermal, moisture, and aerodynamic properties and relates to its surrounding site environment to create the spatial complexity of ecological systems. To understand the dynamics of patterns and processes and their interactions in heterogeneous landscapes such as urban areas, one must be able to quantify accurately the spatial pattern of the landscape and its temporal changes. It is necessary to have a standardized method to define these component surfaces and to detect and map them in repetitive and consistent ways.

Various approaches have been developed in the studies of landscapes in general and urban landscapes in particular in the fields of geography, planning, landscape ecology, natural resources, environmental science, and so on. The land use and land cover approach is a predominant one, especially in geography, planning, and landscape ecology. Land cover can be defined as the biophysical state of Earth's surface and immediate subsurface, including biota, soil, topography, surface water and groundwater, and human structures. In other words, it describes both natural and human-made landscapes of Earth's

surface. Land use can be defined as the human use of the land. Land use involves both the manner in which the biophysical attributes of the land are manipulated and the purpose for which the land is used. However, the relationship between land use and land cover is not always direct and obvious. A single class of land cover may support multiple uses, while a single land use may involve the maintenance of several distinct land covers.

Urban areas are composed of a variety of materials, including different types of artificial materials (concrete, asphalt, metal, plastic, glasses, etc.), soils, rocks, minerals, and green and nonphotosynthetic vegetation. Remote sensing technology has often been applied to map land use or land cover. Each type of land cover may possess unique surface properties (material); however, mapping land covers and materials have different requirements. Land cover mapping needs to consider characteristics in addition to those coming from the material. The surface structure (roughness) may influence the spectral response as much as the intraclass variability. Two different land covers, for example, asphalt roads and composite shingle/tar roofs, may have very similar materials (hydrocarbons) and thus are difficult to discern, although from a material perspective, these surfaces can be mapped accurately with hyperspectral remote sensing techniques. Therefore, land cover mapping requires taking into account the intraclass variability and spectral separability. On the other hand, analysis of land use classes would nearly be impossible with spectral information alone. Additional information, such as spatial, textural, and contextual information, is usually required for a successful land use classification in urban areas.

Traditional methods of land use/cover classification based on detailed fieldwork suffered two major common drawbacks, (1) confusion between land use and land cover and (2) lack of uniformity or comparability in classification schemes, resulting in difficulty in comparing land use patterns over time or between areas. The use of aerial photographs and satellite images since the late 1960s does not solve these problems, since these techniques are based on the formal expression of land use rather than on the actual activities that gave rise to land use patterns. In fact, many land use types cannot be identified

from the air. As a result, mapping of the Earth's surface tends to present a mixture of land use and land cover data, with an emphasis on the latter. Another major problem in urban land use/land cover classification is related to so-called mixed pixels. It is rare that urban land classification can yield an accuracy of greater than 80% by using per-pixel classification (i.e., "hard classification") algorithms. The low accuracy of land use/cover classification in urban areas is largely attributed to the mixed-pixel problem, where several types of land use/cover are contained in one pixel. The mixed-pixel problem results from the fact that the scale of observation fails to correspond to the spatial characteristics of the target. Therefore, the "soft"/fuzzy approach of land use/cover classifications has been applied, in which each pixel is assigned a class membership of each land use/cover type rather than a single label. It has been suggested that characterization and quantification, rather than classification, should be applied to provide a better understanding of the compositions and processes of heterogeneous landscapes such as urban areas. Merrill Ridd proposed a conceptual model for remote sensing analysis of urban landscapes, that is, the vegetation/impervious surface/soil model. It assumes that land cover in urban environments is a linear combination of three components—namely, (1) vegetation, (2) impervious surface, and (3) soil. It has been suggested that this model can be applied to spatial-temporal analyses of urban morphological, biophysical, and human systems. While urban land use information may be more useful in socioeconomic and planning applications, biophysical information that can be directly derived from satellite data is more suitable for describing and quantifying urban structures and processes.

Impervious surfaces are anthropogenic features through which water cannot infiltrate into the soil, such as roads, driveways, sidewalks, parking lots, rooftops, and so on. In recent years, impervious surface has emerged not only as an indicator of the degree of urbanization but also as a major indicator of environmental quality. Impervious surface is found to be inversely related to vegetation cover in urban areas. In other words, as impervious cover increases within a watershed/administrative unit, vegetation cover would

decrease. The percentage of land covered by impervious surfaces varies significantly with land use categories and subcategories. Detecting, monitoring, and analyzing impervious surface is valuable not only for environmental management, for example, water quality assessment and storm water taxation, but also for urban planning, for example, building infrastructure and sustainable urban growth.

Urban Climate and Air Quality

The most remarkable feature of urban climate is the urban heat island (UHI) effect. Urban climatologists have long been interested in the phenomenon that observed ambient air temperature differs between cities and their surrounding rural regions, to which the UHI effect refers. The urban-rural temperature differences are usually modest, averaging less than 1 °C, but they occasionally rise by several degrees when urban, topographical, and meteorological conditions are favorable for the UHI to develop.

Two types of UHI can be distinguished pertinent to the methods of temperature measurement: (1) the urban canopy layer heat island and (2) the urban boundary layer heat island. The former consists of air between the roughness elements, for example, buildings and tree canopies, with an upper boundary just below roof level. The latter is situated above the former, with a lower boundary subject to the influence of urban surface. The spatial pattern of the canopy layer heat island corresponds closely to the distribution of surface cover characteristics. The myriad component surfaces and the spatial complexity when they are mosaicked create a limitless array of energy balance and microclimate systems, preventing urban meteorologists from drawing any generalization. Most of the previous UHI studies have been conducted at the mesoscale using an energy budget approach, which separates the energy flow into measurable interrelated components for simulation modeling. Because the morphological characteristics of urban landscapes that modify urban climate occur at the microscale, it is imperative to have a good understanding of urban morphology.

Knowledge of urban surface energy balance is fundamental to the understanding of UHIs and

urban thermal behavior. If the net horizontal heat advection is not considered, the surface energy balance of a city can be expressed as

$$R_n + A = H + LE + G \text{ (W/m}^2\text{)},$$

where R_n is the net all-wave radiation, A the anthropogenic heat flux, H the sensible heat flux, LE the latent heat flux, and G the net storage heat flux. To quantify the urban surface energy balance, in situ measurements (largely tower based) can be obtained to estimate accurate heat fluxes at the roof level. However, because of the diversity in size, shape, height, composition, and spatial arrangement of the urban “canopy” components, it is difficult to define a surface datum for such measurements, especially for an entire city. Moreover, the sites of the measurements are frequently not associated with meteorological stations. To date, most of the urban heat flux observations have been conducted in a limited number of residential areas. Several experimental studies were conducted in European cities but did not analyze specifically the different components of surface energy balance. Because direct observation of heat fluxes is rare, many efforts have been made to parameterize the terms by using more routinely measured data.

A fundamental problem with the in situ measurements of energy fluxes lies in the great difficulty of selecting a representative site for a larger adjacent region due to the complexity of urban material composition. Sue Grimmond and Catherine South outlined the method to extract surface cover information for the Multi-City Urban Hydrometeorological Database (MUHD). The most noticeable recent advance in terms of instrumentation relates to the use of stand-alone sensors, with which observational data can be recorded for a network in a city. Even with the MUHD and the new sensor technology, siting criteria for urban locations are still hard to define for documenting local-scale heat flux variability. It is extremely difficult and expensive to investigate the detailed spatial pattern of energy fluxes in a city, if cost, time, instrument, and data calibrations are considered all together. Furthermore, the surface energy balance approach has met with mixed success in documenting the temporal variability of energy

fluxes in urban areas. Most of the in situ measurements are used to determine the diurnal variability, but they are less used for evaluating the seasonal and the interyear variability.

Remote sensing studies of urban thermal landscapes and UHIs have been conducted mostly by using NOAA AVHRR data. However, in all these studies, the 1.1-kilometer spatial resolution AVHRR data were found suitable only for large-area urban temperature mapping, not for establishing accurate and meaningful relationships between image-derived values and those measured on the ground. The 120-m (meter)-resolution Landsat Thematic Mapper's (and later the Enhanced Thematic Mapper Plus [ETM+] data of 60 m) thermal infrared data, as well as Terra's ASTER (Advanced Spaceborne Thermal Emission and Reflection Radiometer) images (with spatial resolution of 90 m in thermal infrared bands), have also been extensively used to derive land surface temperature and to study UHIs. Most recent advances include the development and use of quantitative surface descriptors for assessing the interplay between urban material fabric and urban thermal behavior and the use of the landscape ecology approach to assess this interplay across various spatial scales and identify the operational scale of an urban thermal landscape. Because the ASTER sensor collects both daytime and nighttime thermal infrared images, analysis of land surface temperatures has also been conducted for a diurnal contrast. Studies using satellite-derived surface temperatures have identified surface temperature heat islands, which are believed to correspond more closely with the canopy layer heat islands, although a precise transfer function between land surface temperature and the near-ground air temperature is not yet available.

In addition to the UHI phenomenon, rainfall is often higher in the urban area by a margin of 5% to 10%. This increase is attributable to the thermal-induced upward movement of air, increased vertical motions from mechanically induced turbulence, increased cloud and raindrop nuclei, and industrial increases in water vapor. Urban wind speeds tend to be lower because of the rougher surfaces, frequently higher temperatures of the urban fabric, and reduced duration of sunshine due to air pollution.

Urban Air Pollution

Urban areas are associated with sources of a variety of air pollutants and regional pollution problems such as acid rain and photochemical smog. Cities are also major contributors to global air pollution related to ozone depletion and carbon dioxide warming. Within an urban area, the level of pollution varies with the distance to pollution sources, including both stationary and mobile sources (e.g., vehicles). Local pollution patterns in cities are mainly related to the distribution of different land use and land cover categories, the occurrence of water bodies and parks, building and population densities, the division of functional districts, the layout of transportation network, and air flushing rates. Pollution levels tend to rise with land use density, which usually increases toward a city center. Therefore, there is generally an urban-rural gradient in the concentrations of air pollutants. For example, the concentrations of particulates, carbon dioxide, and nitrate ion (an oxide, as in acid rain) in the inner city are typically two to three times higher than in the suburban areas and five times higher than in the rural areas.

Furthermore, urban areas experience another type of pollution—heat pollution. Because of the construction of tall and closely spaced buildings, the flushing capability of the air at the ground level is largely reduced. However, the relationship between air pollution and urban heat has not been fully understood, although both relate to the pattern of urban land uses. UHIs favor the development of air pollution problems but are not indicators of air pollution. Higher urban temperatures generally result in higher ozone levels due to increased ground-level ozone production. Moreover, higher urban temperatures result in increased energy use, mostly due to the greater demand for air conditioning. As power plants burn more fossil fuels, the pollution level is driven up. A few studies have so far examined the correlation between land surface temperature and air pollution measurements.

Urban Water

The process of urbanization has a considerable hydrological impact in terms of influencing the

nature of runoff and other hydrological characteristics, delivering pollutants to rivers, and controlling rates of erosion. One of the most notable impacts is the way in which urbanization affects flood runoff. Because urbanization replaces land surface with nonevaporating and nonporous materials, there is a trend for flood runoff to increase in comparison with rural areas. Urban drainage densities may be greater than the rural densities, and the installation of sewers and storm drains accelerates runoff. As a result, the rainfall-runoff process in an urban area tends to be quite different from that in natural conditions depicted in classical hydrological cycles. Peak discharges are higher and occur sooner after runoff starts in basins. It should be noted that this effect of urbanization varies according to the size of flood. As the size of flood becomes larger and its recurrence interval increases, the effect of urbanization tends to decrease.

Urban warming changes the moisture characteristics, precipitation amount, and storm characteristics in the urban areas. Higher air temperatures hold more moisture, and warmer water increases the moisture content of storms. Urban warming often increases precipitation amount and storm frequency and intensity. Global warming relocates precipitation globally, so that some places may experience unusually wet and others unusually dry conditions. Moreover, watersheds with large amounts of impervious cover may experience an overall decrease in groundwater recharge and baseflow and an increase in storm flow and flood frequency. Imperviousness is also related to the water quality of a drainage basin and its receiving streams, lakes, and ponds. Increase in impervious cover and runoff directly affects the transport of nonpoint source pollutants, including pathogens, nutrients, toxic contaminants, and sediment. Increases in runoff volume and discharge rates, in conjunction with nonpoint source pollution, will inevitably alter in-stream and riparian habitats, resulting in the loss of some critical aquatic habitats. Some measures for mitigation have been suggested, including the construction of porous pavements and neighborhood detention ponds and wetlands to collect storm water. To increase evapotranspiration, various types and shapes of green spaces, green roofs, and green walls are advocated. In sum, urban areas have a unique feature in water balance.

Urban Vegetation

In the process of urbanization, natural vegetation cover is largely replaced by paved surfaces. Open spaces are maintained for recreational or ornamental purposes rather than for the production of food or timber, so that the ecosystem dynamics of the remaining “green” areas of the city are usually quite different from those of the open countryside. The use of exotic species in urban areas seems to suggest an increase in species diversity, but many of these exotic species are very rare and restricted to certain locations. Moreover, the levels of use of fertilizers and pesticides per unit area in cities are usually much higher than on agricultural land, with corresponding environmental effects. Species diversity is kept low by the ruthless pursuit of weeds and pests. The contribution of exotic species to urban ecological complexity is thus insignificant. Furthermore, urban vegetation grows in an environment remarkably different from natural vegetation. Impervious surfaces prevent rainwater from recharging the groundwater, making less water resources available for urban vegetation. In the meantime, impervious surfaces are easy to heat up due to low specific heat capacity. Recent studies based on satellite observation found that the UHI effect changes vegetation phenology. Intensive management can significantly enhance carbon storage by urban vegetation.

Urban Environmental Sustainability

To define various strategies for urban sustainable development in the context of accelerated urbanization and global climate change, urban planning, resources, and environmental management and governance strategies need to be examined and evaluated. Among the key challenges of the current era are the range, complexity, and intertwining nature of environmental problems in the urban areas and the limited response capacity and capability of cities, in developed countries as well as in developing ones. It is imperative to understand fully the science, technology, and policy issues in urban environmental studies and how they interplay in a particular social, economic, political, and cultural context. Policies, regulations, impact adaptation, mitigation, and remediation can intervene in the urban environmental

system by reducing or enhancing the negative feedbacks. Technologies such as modeling, statistical analyses, geospatial techniques, and digital cities have effects on both the science and the governance. The interdisciplinary nature of urban environmental problems often requires an interdisciplinary team approach to address them.

URBAN GARDENS

Urban gardens can be described as private green spaces belonging to a property within towns and cities. They vary in size from a relatively small patch of green space situated in front of a domestic property, often found in inner-city areas to large spaces surrounding an individual property, exceeding several hundred square meters. Urban gardens provide a haven for a wide range of flora and fauna within urban areas. The urban garden is generally not believed to be exceptional in its species richness, yet it has higher plant diversity than is found in the Amazon rain forest. Many bird species also frequent urban gardens, adding a sense of character to a neighborhood, especially during the summer months.

To understand the benefits of urban gardens, it is useful to explore some of their significant characteristics. These include the following:

1. High plant diversity
2. Large number of food chains
3. Large number of unique habitat zones
4. Constant state of succession
5. Disturbed state

The relatively high plant diversity reflects that fact that many gardeners plant as many species as possible. This phenomenon has a knock-on effect, since the numerous varieties of plant species provide the basis for a different food chain. Gardeners are usually keen to create several zones within a garden, such as a water feature, a flowerbed, lawns and hedges, and so on, each of which supports different types of flora and fauna. A constant state of succession is ensured by not allowing a particular plant species to dominate. This has the added advantage of preventing a garden from supporting only a specific plant species such as woodland. Finally, because the garden is continuously subjected to disturbance, it is generally welcoming of foreign species, thus ensuring diversity.

Urban gardens provide a range of benefits to an urban area that are not widely acknowledged. Vegetation is known to have a substantial effect on the temperature, moisture, and precipitation regimes of urban areas. For instance, plants can reduce temperatures by as much as several degrees Celsius in large urban green spaces by increasing the relative humidity of the air, causing it to cool, and counteracting the urban heat island effect. Indeed, a large tree, well supplied with water, has the ability to provide local cooling equivalent to several air conditioners running over much of a day.

Urban gardens have the potential to provide significant benefits to human well-being. In the United States, for example, a study found gardeners consistently reporting the importance of urban gardens in providing an opportunity for exercise and reduction in stress levels. In a U.K. survey, gardeners cited the creation of a pleasant environment and the promotion of relaxation as the two most important aspects of gardens. Other benefits noted were personal satisfaction gained through maintenance and in producing a tidy piece of green space, the health benefits of fresh air and

Bird's-eye view of a park six stories above the ground in downtown Tokyo

exercise, a sense of peace and tranquility, and the opportunity to meet and talk with neighbors.

Despite their crucial role in urban society, there is generally a lack of information on the extent of urban garden space because local government is not required to monitor or manage such spaces, yet it is apparent from aerial photography and other sources that they constitute a significant portion of many urban properties and must therefore constitute a sizable proportion of urban areas. This relatively large aggregated green space has the advantage of another very significant feature, namely, flood alleviation. As climate change begins to produce more extreme events such as floods, urban gardens have the distinct advantage of attenuating flood peaks.

Urban gardens form a large part of the public face of a household and its owners and may display a “neighbor mimicry effect,” whereby proximal gardens share significantly more characteristics than distal gardens. Urban front gardens, in particular those that look similar, in terms of their form and the types of vegetation present, may be found close to each other along street sections. This apparent mimicry effect could be very important in deciding important landscape changes in areas where planning authorities have little influence.

Given the numerous benefits of urban gardens, it is surprising to find that they are facing increased threat for several reasons. These include increased car ownership, difficulty of on-street parking,

poor public transport, and a fashion for low-maintenance minimalist landscape. Fear of car crime or robbery while walking from the car to the house has also been cited as a reason to park on front gardens.

URBAN GEOGRAPHY

The dawn of the 21st century ushered in an era when, for the first time in the history of humanity, the majority of people on the planet live in urban areas. More than ever before, cities are now at the core of defining the human experience, for better or for worse. In this context, urban geography is eminently positioned as a field that can enhance our understanding of the structure, form, and function of cities, explain the process of urbanization and the dynamics of urbanism, and offer valuable insights into an equitable and sustainable urban future.

Indeed, more than ever before, urban geography is one of the most vibrant and productive areas of inquiry in the discipline. The volume of scholarly work that focuses on the multitude of urban-related topics that have attracted the attention of geographers has shown an unabated trajectory of quantitative growth and qualitative sophistication. At the end of the first decade of the 21st century, the momentum not only seems to have carried the subfield to the center of attention of geography as a whole but, in many ways, has been instrumental in the recognition of the contributions of geographers to the broader field of urban studies and affine disciplines such as sociology, urban planning, political science, anthropology, and so on. To take stock of where urban geography stands today and where it might go in the future, it is useful to briefly retrace whence it came, if only in very broad strokes.

Origins and Growth of Urban Geography

The emergence of urban geography can be traced back to 19th-century discussions of urban origins and growth. The early emphasis on the site and situation of settlements and their role as centers of civilization was linked to geographers' overarching interest in the relation of humans to their physical environment. This abiding concern with excavating the rise of cities and the role of environmental conditions—whether physiographic or climatic—in shaping society reflected the broader disciplinary concerns of early geographers in arriving at scientific explanations that bridged the gap between the physical sciences

and the incipient social sciences. It also hinged on an ultimately flawed reliance on assumptions that the natural environment exerted a determining influence on human society and behavior, as well as on the structure, form, and function of its spatial arrangements. In effect, such geographers would argue that the site of a city determines—not merely influences—the prospects of its social development and economic growth. Two of the more prominent figures in this particular perspective were the American geographers Ellen Churchill Semple and Ellsworth Huntington. Their work and that of their colleagues was challenged in the 1920s as overly simplistic and deterministic. The debunking of environmental determinism acted as a dead end for the sort of human-environment work that had emerged in the early decades of geography's disciplinary development and that had definitively moved urban geography into a different direction altogether.

Early on, the environmental-determinist paradigm was matched in popularity by a growing interest in the regional patterns of settlement and in the classification of urban structure, form, and function. Early works such as Frederick Emerson's 1907 study, *A Geographical Interpretation of New York*, or Almon E. Parkins's 1918 volume, *The Historical Geography of Detroit*, were among the founding texts of this particular tradition in urban geography. In most cases, copious descriptive information was compiled with little attempt made to offer anything more analytical. This empiricist paradigm, too, was ultimately inadequate in providing a sustained analytical framework because of its inherent limitations as an almost exclusively descriptive approach. Nevertheless, the regional description paradigm served the discipline well in preparing the way for more analytically refined approaches that shifted the focus of geographical inquiry from the environment alone to socioeconomic conditions and their spatial patterns.

Key in this regard was the influence of the Chicago School, which became a catalyst in promoting both the growing interest in analyzing cities and the emerging concern with understanding the links between socioeconomic conditions and spatial patterns. This approach was pioneered by researchers in the sociology department at the University of Chicago in the 1920s and 1930s, using

the city of Chicago as an urban "laboratory." A seminal text of this tradition was the famous volume by Robert Park and Ernest Burgess, *The City*, first published in 1925. A core element of the Chicago School approach was the axiomatic acceptance of the proposition that human society reflects natural processes and, as such, is conditioned by "natural laws" that apply to it just as much as they apply to plant communities, for example. Nevertheless, despite the reluctance of the Chicago School to irrevocably sever the threads to the organismic analogy between society and nature, its development signaled the transition to more positivist methodologies, with their emphasis on the "scientific method," as well as a more nomothetic inclination that sought to determine universal laws. Of special interest is the use of ethnography as a tool in discovering the links between social relations and their spatial arrangements, a method that would gain renewed currency several decades later. Most important, at the time, the focus of the Chicago School on mapping groups and institutions in the urban landscape was well suited to the interests of geographers, who were heartened by this spatial turn in the social sciences and embraced the work of their sociologist colleagues.

In particular, the keen interest of the Chicago School to abstract the spatial patterns of the city into models that captured salient aspects of the social order and urban structure fueled the growth of interest in urban geography. Ernest Burgess's concentric zone model and Homer Hoyt's sector model became clarion calls for visualizing the interplay of social and spatial processes. Many young geographers, eager to solidify the credentials of their discipline as a scientific enterprise, immersed themselves with relish in modeling. Chauncy Harris and Edward Ullman's multiple-nuclei model represented just one of the more sophisticated refinements that geographers contributed to the study of cities. Of special significance is that the work of social scientists—not the least geographers—in this vein of research eventually led to the development of factorial ecology in the 1970s that used multivariate statistical techniques to examine residential differentiation in urban areas. In this sense, the Chicago School was an important antecedent for the robust urban geography that spread across Anglo-American geography departments in the 1950s and 1960s.

An aerial view of Chicago. Chicago played a key role in the rise of urban studies, including urban geography.

The parallel—albeit discrete—development of central place theory in interwar Germany, in the work of the geographer Walter Christaller and the economist August Lösch, was to influence a great number of geographers in the post-World War II period and directly contribute to the rapid expansion of Anglo-American urban geography. The focus of their work, and that of their successors outside Germany, was on modeling the optimal spatial distribution of settlements and, especially, to explain the size, spacing, and function of smaller settlements in the urban hierarchy. The four basic concepts were (1) centrality, (2) range, (3) threshold, and (4) hexagonal trade areas. These were based on assumptions that consumers behave rationally and that they operate on an isotropic plane—a uniform landscape devoid of physical or human-made obstacles or hazards.

The effect of these general tendencies to abstraction and theory development was the inevitable emergence of an urban geography as a full-fledged spatial science by the 1950s and 1960s. With the whirlwind of spatial science unleashed, urban geographers immersed themselves in a matrix of spatial variables and spatial systems. Whereas previous generations of geographers had looked at geology or biology for inspiration, this generation was more focused on mathematical statistics and physics, or “social physics” to use the moniker of the day. The intensive quantification of the work that urban geographers were performing mirrored similar developments in other social sciences, to one extent or another. This particular paradigm culminated, perhaps, with the publication of David Harvey’s *Explanation in Geography* of 1969, widely hailed as a landmark text for the field. Nevertheless, a sustained reaction had

already been mobilized in an effort to counter the abstraction inherent in spatial science and to ground urban geography in a less abstract, albeit still positivist, approach that had human behavior at its core.

Behavioral and Humanist Perspectives on Urban Geography

Starting in the mid 1960s, the behavioral thread of urban geography focused on the cognitive processes by which human subjects made decisions. This was less a rejection of urban geography as spatial science than a rescaling of the research conducted to a human dimension rather than the aggregate dimension necessary for work in spatial science. Behavioralism retained much of the positivism of the previous approaches, but the guiding principle was that the analysis of the daily spatial behavior of individuals and the exploration of how individuals experienced and responded to places would provide a deeper understanding of urbanism and urbanization. Some of the core statements of this approach can be found in Julian Wolpert's 1964 article in the *Annals of the Association of American Geographers*, "The Decision Process in Spatial Context," and Allan Pred's 1967 monograph, *Behavior and Location: Foundations for a Geographic and Dynamic Location Theory*.

The behavioral turn was a significant development in urban geography, primarily because it initiated a thread that rejected the aggregate scale of spatial science for a more human orientation. Nevertheless, as would be expected of such a dynamic discipline, right away there were plenty of geographers who argued that the behavioralists were too timid in their critiques of spatial science and that they were not really going far enough to explore the human dimensions of urban life. Inspired by the philosophical currents of phenomenology/existentialism that were quite popular in continental Europe in the post-World War II period, humanist urban geographers sought to break away from the positivist methodologies that dominated the discipline. They favored, instead, methods such as textual analysis and ethnography, the latter having an antecedent in the work of the Chicago School a few decades earlier. Humanistic urban geography embraced the individual as an agent and sought to understand the

subjectivities of his or her lived experiences in the city. The notion of space yielded its role as an organizing concept for the discipline to a more subjective notion of place. What mattered to the humanists was to extract the significance that individuals attach to places as the sites of their lived experiences. To do so, the humanist urban geographer must enter the "life-world" of the subject to glean the meanings attached to the places experienced by the human consciousness. Just as important, the humanist seeks to understand the ways by which that human consciousness actively reconfigures places in the lives of human subjects through intersubjectivity. Edward Relph's 1976 classic *Place and Placelessness* and Yi-Fu Tuan's 1976 work *Topophilia* became the essential texts of this turn in geography, influencing a generation of urban geographers.

The Radical Turn

Parallel to the behavioralist/humanist rejection of spatial science in the mid 1960s was a growing concern with the relevance of the work done by urban geographers. In the spirit of the times, a growing number of young geographers were influenced by the antiwar movement, the civil rights struggles, and the realization that large populations in the inner cities were socially marginalized and spatially segregated. The political upheavals and social struggles of the 1960s were a catalyst for the formation of radical tendencies, especially among urban geographers, that moved more and more to the left, identifying with the emancipatory aspirations and theoretical positions of Marxism. These urban geographers reached back to the work of Friedrich Engels's 1844 *The Condition of the Working Class in England in 1844* and the voluminous opus of Karl Marx to reject the academic abstractions of spatial science that were increasingly seen as amoral at best or complicit in oppression at worst. Motivated, in part, by the rediscovery of Marx, especially through the interpretive lens of Western Marxism, young radicals took to heart the dictum that philosophers have only interpreted the world in various ways and that the point was to change it.

An important development in the United States was the inauguration, in 1969, of the radical journal *Antipode*, which provided a venue for

radical urban geographers to publish their heterodox work. Another seminal event in the radicalization of urban geography in those early days was the publication of David Harvey's 1973 *Social Justice and the City*. Confronted with images of crushing urban poverty, racial segregation, widespread public and private disinvestment in the city, clashes in the streets with the police, burning city neighborhoods, and a host of other jarring urban phenomena in the most advanced capitalist economy in the world, it became an urgent preoccupation for radical urban geographers to explain and address what they were witnessing. They rejected what they perceived to be the voluntarism of the behavioralists and humanists with their emphasis on the individual as an agent. They sought, instead, to make use of radical political economy as a method to expose the profligate economic, political, and social structures that underpinned the injustices at the core of the capitalist system, oppressing the working class, women, and minorities, especially in the cities of the United States and other "First World" countries. In 1980, Edward Soja introduced the concept of the "sociospatial dialectic" in an article by that title in the pages of the *Annals of the Association of American Geographers*. The self-evident notion that the social and the spatial are inextricably intertwined and that one cannot be properly understood without the other became an organizing principle for radical urban geographers such as Harvey, Neil Smith, and Soja. Influenced, in part, by the work of the French philosopher Henri Lefebvre, who argued that space is a social product and who asserted the centrality of space in organizing and sustaining capitalism, these radical urban geographers embraced a more nuanced and subjective perspective relative to earlier Marxist analyses. In their work, Marxism was spatialized, and the social relations and spatial practices that constitute the city were subjected to a relentless scrutiny.

In the early 1970s, the terms *structuralist* and *Marxist* were used to describe radical urban geographers who engaged with the voluntarists/humanists in a set of protracted disputations that defined the general theoretical and methodological contours of urban geography. Over the years, there have been several refinements and

restatements of the respective arguments in a dialectical exchange that has been quite productive and has propelled urban geography to a place of prominence in the discipline and in the broader social sciences. One illustrative example has been the way in which the two camps have engaged the question of gentrification in North American cities during the 1980s and 1990s. On the one hand, the geographer Neil Smith authored a series of articles starting in 1979 and culminating with the publication, in 1996, of his book *The New Urban Frontier: Gentrification and the Revanchist City*. Smith's arguments were unabashedly of Marxist provenance and emphasized the role of structural forces, including real estate speculation and land prices, as the prime impetus behind gentrification. On the other hand, the geographer David Ley approached the same question with a humanist's sensibility, insisting on human agency as the driving force behind gentrification. His contributions to the heated discussions through the 1980s culminated in 1996 with the book *The New Middle Class and the Remaking of the Central City*. Geographers were joined by researchers from other disciplines in this academic melee throughout the 1980s and into the next decade, signaling a new currency for urban geography.

"Post-al" Encounters in Urban Geography

A seminal development during the late 20th century was the emergence of a poststructuralist position that would lead to a number of *post-al* approaches to the study of cities: postmodernism, post-Marxism, postfeminism, postcolonialism, and so on. Building on humanist disaffection with structural explanations—and heavily influenced by the development in literary criticism of a derivative, Anglophonic reading of translations of what the French called *la pensée* 1968—some urban geographers challenged what they saw as the totalizing, deterministic straightjacket of the Marxist analysis of cities. Part of a "cultural turn" in geography, *post-al* urban geographers in the 1980s and 1990s delved into the study of culture in the city. Gender, race, ethnicity, and sexuality were very much on the agenda, rectifying the considerable degree of neglect that the silences of earlier urban geographies had bequeathed the field. What emerged was a definitive rejection of

even the hint of positivism, a diligent abjuring of structural explanations, an embrace of multiple perspectives, and a preoccupation with discourse and ideology. Citing French authors became fashionable, with the names of Foucault, de Certeau, Bourdieu, Lyotard, Baudrillard, Deleuze, Guattari, Irigaray, Cixous, and others used liberally in the writings and speeches of a new brood of urban geographers. This change coincided with the “spatial turn” across the social sciences and the humanities, where space and the geographical imaginary were discovered and embraced. This step brought scholars from other disciplines in contact with the work of geographers, creating a vibrant interdisciplinary exchange that focused on urban space and spatiality. All of a sudden, literary theorists, sociologists, anthropologists, and other scholars were assiduously quoting urban geographers, while urban geographers picked up where their humanist predecessors had left off and merrily sauntered further afield into literatures hitherto beyond their range. Literary criticism and psychoanalysis, for example, were no longer distant precincts but, rather, fruitful fields for cross-pollination for work on urban space and spatiality in the post-modern era. This development has coincided with the announcement of the existence of a Los Angeles School of urbanism to replace the void left by the Chicago School decades ago. According to the geographer Michael Dear’s 2001 edited volume *From Chicago to L.A.: Making Sense of Urban Theory*, the Los Angeles School is characterized by a move away from the modernism of the Chicago approach to a more postmodern vision that draws its inspiration from the fragmented and decentered nature of the sprawling metropolis in Southern California.

The infusion of post-al attitude and latitude invigorated both Marxist and non-Marxist urban geographers and contributed to the further development of the boisterous critical urban geography that one encounters today. What makes urban geography “critical” is a skeptical posture that interrogates what is taken for granted about the social relations and spatial practices in urban areas. It is a big tent under which are accommodated epigones of radical and humanistic geography alike, in a collegial conviviality that bears similarities to a marriage of convenience. Nevertheless,

despite the constant spats, the palpable suspicion, and the unmitigated irreconcilability that seems to mark critical urban geography, it has produced an important body of work that has secured, to a substantial degree, its bona fides within the academy. Global city regions, transnational urbanism, the right to the city, spaces of consumption, the embodiment of the urban experience, virtual urbanities, urban surveillance, and the mobilities and materialities of urban space are all common threads of inquiry for critical urban geographers alongside more persistent themes such as urbanization, segregation, governance and urban politics, or the effects of neoliberal economic policies on metropolitan areas.

More recently, the environment reentered the picture after decades of exile, in the form of urban political ecology. Drawing from critical urban geography as much as from political ecology, geographers have rediscovered nature in the city. Unlike the earlier environmental turns of the determinists or human ecologists, however, today’s urban political ecologists do not fasten onto ontological assumptions about nature, nor are they preoccupied with organismic analogies. Rather, they posit nature as the hybrid of human and nonhuman processes that are both physical and cognitive. As such, what emerges is a rigorous analysis that examines the social production of urban environments and the complex articulation of nature and the city, in a project that harkens back to the egalitarian and emancipatory intentions of radical urban geographers. In Nik Heynen, Erick Swyngedouw, and Maria Kaika’s edited volume *In the Nature of Cities: Urban Political Ecology and the Politics of Urban Metabolism*, one can glimpse the sprawling and ambitious agenda of this paradigm that combines the concerns of a socialized ecology with a spatialized political economy in an era of inexorable urbanization.

Finally, the perennially gnawing question of relevancy has led urban geographers to another seemingly atavistic turn. Just like nature and the environment have found a place in 21st-century urban geography, increasingly a more empirical geography has emerged to reclaim currency and credibility in the discipline. Advances in geographical information technology have fueled an interest in an applied urban geography that, in a way, harkens back to spatial science. This time,

however, the byword is *mixed methods*, diligently integrating quantitative and qualitative approaches. Thus, geographic information systems (GIS) and statistical methods have joined ethnography and other qualitative methodologies to create integrated analyses of urban phenomena that affect the lives of real people in real communities. It is generally thought that this new applied urban geography is better positioned to effect change and affect the lives of urban communities in a progressive direction because it provides needed analysis that can influence policy making. One recent example of this sort of work has been the research on the effects of subprime mortgages and foreclosures on the working class and people of color done by Elvin Wyly, Dan Hammel, Kathe Newman, and others.

In conclusion, today urban geography is more diverse and spirited than ever. In the Association of American Geographers, and its equivalent professional organizations in Canada and the United Kingdom, urban geography's preeminence as a popular subfield or specialty is rivaled only by the number of geographers engaged in GIS work. The "spatial turn" in the social sciences and the humanities has clearly given geographers currency among other scholars studying urbanization and urbanism. At the same time, urban geographers have drawn on the rich and varied history of their discipline to forge a dynamic field of inquiry that rightfully claims a central role in the development of geography and its engagement with other disciplines.

being colonized by pioneer plant species. The definition might reasonably be expanded to include freshwater and marine environments. Thus, urban green space includes iconic sites such as London's Hyde Park and New York's Central Park, large expanses of seminatural vegetation such as Perth's Kings Park and Botanic Garden, and abandoned sites such as can be found in all cities. Irrespective of their form, urban green spaces are perceived in many ways by those who encounter and use them. For many people urban green spaces are places that enhance physical and psychological well-being by providing contact with the "natural" world, yet for others they are places of fear or spaces that serve to reinforce social boundaries. This entry first defines ecology *in* cities and the ecology *of* cities and examines the contributions urban green spaces can make in terms of environmental services, engineered urban green space, social and cultural services, and health and well-being. Negative outcomes and perceptions of urban green space are then examined. The entry concludes with a look at the future of the many forms of urban green space.

Homo sapiens is rapidly becoming a predominantly urban(ized) species. At the beginning of the 20th century, only 10% of the world's people lived in urban areas; that number now stands at more than 50% and continues to grow. Ongoing urbanization and the growth of megacities pose threats to biodiversity, dramatically alter climatic and hydrologic processes in urban environments and the surrounding landscapes, and threaten to isolate humans living in cities from "nature" as urban green spaces are lost to development and infilling. Nevertheless, many urban areas contain a surprising amount of green space. These "urban green spaces," in their many forms, provide a wide range of environmental and sociocultural services to city dwellers, including those related to health, education, and recreation. Such spaces are playing an increasingly central role in integrated regional and urban planning and design.

URBAN GREEN SPACE

Urban green space, which is related to, but not necessarily the same as, an urban ecosystem and green infrastructure, comes in a variety of forms and serves a variety of purposes in the urban landscape (see the first set of photos). Various types of urban green space are recognized in the literature: planned or unplanned remnant intact patches of vegetation embedded in the urban matrix, planned spaces such as parks or restored areas, and abandoned or derelict sites that are slowly

Ecology in and of Cities

There is a long tradition of studying and documenting the ecology of urban green spaces in cities, such as the descriptions of the plant species that colonized bombed sites in the aftermath of

Examples of urban green space in Auckland, New Zealand: (A) Albert Park in the inner city; (B) restored Waiatarua wetland, Meadowbank; (C) recreational space, Dunkirk Reserve, Point England; and (D) the author's back garden. Note that all these spaces are multifunctional and provide both environmental and sociocultural services.

World War II. In the early 1990s, however, urban ecology rose to prominence as a subdiscipline of ecology. Urban ecology has taken two broad approaches: (1) the study of ecology *in* cities and (2) the study of the ecology *of* cities. The former is concerned with understanding the composition, structure, and function of the populations of organisms and the habitats in which they live in cities; the latter uses the tools and concepts of ecology, such as the quantification of biogeochemical fluxes and ecological footprints, to study cities as ecological systems.

Ecology in cities faces several challenges, including the loss of habitat; air, soil, and water pollution; the direct and indirect threats of invasive species; and climate change. Despite such threats to biodiversity, many cities are surprisingly

“green” and are often extremely spatially heterogeneous. For instance, two thirds of the Greater London area (158,000 ha [hectares]) comprises green space of some type, 20% of the total area is considered to be valuable wildlife habitat, and 16% is protected in some way; many threatened and iconic species can be found within this area, including the stag beetle (*Lucanus cervus*). Similarly, urban waterways, including artificial structures, in Northern New Zealand (e.g., Hamilton and Auckland) contain significant populations of native fish, such as the endemic banded kokopu (*Galaxias fasciatus*). The common view of urban expanses as “biological deserts” does not sustain scrutiny; indeed, per unit area, domestic gardens may have levels of species richness approaching those of tropical rain forests.

Environmental Services

Urban green spaces are not simply refugia for rare (or other) plant and animal species. They can also modify and ameliorate biophysical processes and so have become useful tools for urban planning (in which context they are sometimes called *green infrastructure*). In terms of the physical environment, urban green space can improve local air and water quality, filter wind and sound, and counteract the elevated temperatures produced by the urban heat island. Significant temperature differences between parks and built-up areas have been recorded, with these differences extending over hundreds of meters; bodies of water in the urban landscape provide similar cooling effects. Urban green spaces can also provide environmental services to nonurban parts of the landscape (see wildlife corridor photos). For example, populations of the bird species Tui (*Prosthemadera novaeseelandiae*) in the Waikato (Northern New Zealand) use urban plants to supplement their food supply. This is particularly important during times of the year when native plants are not flowering. Tui living in remnant patches of native forest outside urban areas commute into urban areas to exploit these nectar sources. Thus, urban green space provides a wide range of valuable environmental services both within and beyond the urban environments within which they are located.

Engineered Urban Green Space

As the environmental services that urban green spaces provide have become increasingly valued, there has been growing consideration of how green spaces can and should be included in urban design and planning. Low impact urban development and design (LIUDD) emphasizes the utility of green infrastructure, with a focus on the amelioration and management of the urban water cycle. The retention of urban green space can reduce the amount of impervious surfaces in urban catchments; these surfaces are associated with (a) dramatic shifts in storm hydrographs (especially increased “flashiness”) and (b) the flux of sediments and undesirable contaminants into waterways. As an example, New Zealand’s largest urban wetland restoration project, Waia-tarua wetland in Meadowbank, Auckland, was restored in the 1990s in an effort to trap sediments in storm water runoff from the surrounding catchments; of the 130 metric tons of contaminants and sediment flowing through this system prerestoration, a significant fraction is now retained in the wetland. The project has had other positive effects, such as providing a recreational resource and an increasing habitat for waterfowl (including kotuku, *Egretta alba modesta*) (see first set of photos). LIUDD also encourages the implementation of microlevel urban

green spaces such as green roofs and rain gardens (both designed for increased water retention and/or biofiltration).

Wildlife corridors provide another example of engineered urban green spaces, with their primary purpose being improving ecological connectivity in urban environments but with the added benefit of increasing the quantity of urban green space (see wildlife corridors photo). Wildlife corridors are designed to link isolated populations together, with the goal of facilitating the flow of individuals and genes between isolated local populations, and to allow mobile species to move through fragmented landscapes.

Social and Cultural Services

Urban green spaces are places where ecological and human-social systems come together. Besides their environmental benefits, urban green spaces provide social and cultural services. As well as being associated with improved physical and psychological health and even increased longevity, they also provide valuable resources for recreation and learning. Furthermore, urban green space can also have benefits in the wider community by developing social ties and attachment to the community by promoting individual interactions—this is an indirect benefit of, for instance, community-driven urban restoration projects. Recent studies have even suggested that vegetation may reduce crime levels, despite the fear that urban green spaces are often centers of antisocial behavior.

Health and Well-Being

Urban green space provides many health services, both physical and psychological. Konstantinos Tzoulas and colleagues have suggested that urban green space provides health benefits in two ways: (1) by improving the local environment, they promote physical activity and so physical health and well-being and (2) passive viewing of green space after negative experiences (e.g., hospitalization) can boost psychological health and well-being. The use of urban green spaces for physical exercise and recreation is a visible example of the health benefits such environments provide. Studies (controlled for age

and sex) associate the availability of green space with increased exercise levels, although the evidence for the quality and proximity of urban green space alone being directly related to physical activity among local populations is equivocal.

The second mechanism by which urban green spaces provide sociocultural benefits is more subtle. Roger Ulrich reported in 1984 that hospital patients who could see natural environments recovered significantly faster from surgery than those with more limited views. Subsequent research has reinforced the links between exposure to urban green space and psychological health across a broad section of society. Exposure to and interaction with “nature,” which for those living in cities will often be limited to urban green spaces, has been argued by child psychologists as playing a crucial role in children’s cognitive, emotional, and social well-being. There is some concern, therefore, over the diminishing access to nature (as urban green space declines) and the increasingly sporadic (in time) interactions children have with it. As one example of the benefits associated with providing children access to nature, there is a growing awareness that there are links between “attention” and children’s access to and use of green space. The engagement of children who have attention deficit hyperactivity disorder with green space has been associated with the reduction of symptoms.

A Downside?

Despite the many benefits associated with urban green spaces, they are also associated with some negative outcomes and perceptions. In particular, people may see urban green spaces as dangerous places where crimes are likely to occur. In this context, the nature of the green space is particularly important; derelict and/or poorly maintained green spaces are perceived very differently than well-maintained ones.

Rather than strengthening links between different members of the community, urban green spaces can sometimes serve to act as boundaries that reinforce socioeconomic division and segregation. Some authors have argued that the poor park conditions in Roxbury and North Dorchester near Boston imply low levels of local interest and little pressure on local municipalities to maintain

parks and that low levels of local interest are associated with disenfranchisement and segregation.

In terms of human interaction with urban green spaces and the wildlife that use them, problem issues include increased human-wildlife conflict and the potential for urban green space, especially in peri-urban environments, to act as reservoirs for disease. For example, links between suburban expansion, tick abundance, and the growing incidence of Lyme disease in North America are well documented. Interactions between humans and green space in urban environments are complicated, and understanding them is not just a case of “the more, the better.”

The Future

Urban green space encompasses many forms, including remnants of “natural” vegetation, restored environments, and human-made or engineered spaces. These spaces provide important environmental and sociocultural services to organisms, including humans, using and living in urban environments. A growing body of research considers ecology in and the ecology of cities and the many services that urban green spaces provide. Despite the considerable environmental and sociocultural services provided by urban green spaces, how best to integrate such areas into urban planning and design remains an open question. Urban environments are experiencing, at an accelerated rate, many of the environmental changes facing the planet as a whole—elevated temperatures; dramatically altered hydrological systems; air, water, and soil pollution; and habitat loss. We have much to learn from how urban green spaces respond to such pressures and how they can be used to respond to the social and environmental changes such pressures will bring.

URBAN HEAT ISLAND

Urban areas often experience warmer temperatures than their surrounding rural areas. This phenomenon, called the urban heat island (UHI) effect, has been observed in numerous settlements around the world, making it one of best-documented examples of inadvertent climate modification. Heat islands occur in the air, at the surface, and in the ground beneath cities. Atmospheric heat islands may extend to considerable distances aloft, although UHIs occurring below roof level in the urban canopy layer have received the most attention in the literature. As an increasing proportion of the world’s population lives in urban areas, cities grow, and their impact on environmental, biophysical, and atmospheric processes increases. This entry provides a brief overview of UHI impacts, describes the physical causes of UHIs, and closes with a brief synopsis of urban climate research.

May 19, 1998: Hot rooftops shine brightly in a fresh, false-color image of Baton Rouge, Louisiana, taken as part of the Urban Heat Island Pilot Project (UHIPP) conducted by NASA and other agencies. It clearly demonstrates the principle behind UHIPP—that the differences in cooling and heating between the natural and humanmade surfaces can affect city temperatures.

Source: NASA/Marshall Space Flight Center.

Urban heat islands directly affect a number of human and natural systems. UHIs also generate indirect impacts through altering mesoscale circulations such as thunderstorms and urban/country breezes. Urban gardeners are well aware that

the UHI alters flowering dates and extends the growing season in cities. Urban warmth can be favorable for many species of plants and animals, particularly during the cool seasons. Conversely, elevated urban temperatures often negatively

affect human comfort and health during warm seasons. Sensitive demographic cohorts such as the elderly and infirm are at particularly high risk of heat-related illnesses and mortality. Energy demands are also affected by the UHI. In warm climates, the higher number of cooling degree days occurring within cities further increases cooling costs. In cool climates, however, energy savings from reduced heating degree days may offset or surpass the increased cooling bills. Even climate science is affected by the UHI since artificially high temperatures can introduce bias into long-term temperature records. If land use/land cover is changed in the vicinity of a weather station, localized climatic changes could appear in the station's record and be misinterpreted as a regional or even global signal of climate change. Removing this urban bias requires sophisticated statistical techniques. The influence of urban areas on large-scale temperature trends continues to attract attention among climatologists.

UHIs are not limited to large cities; small towns generate heat islands too. In fact, any place where artificial land cover has replaced natural land cover could have a climate that is different from its surroundings. Replacing natural land covers, such as trees and grass, with artificial land covers, such as concrete and asphalt, alters the local energy balance. First of all, more incoming energy is retained in urban areas than in rural areas. Many urban surfaces have a low albedo (reflectivity) and often absorb more solar energy than the natural land covers they have replaced. In addition, the geometry of street canyons causes multiple reflections within the canyon, allowing multiple opportunities for building materials to absorb energy. Along with the aforementioned characteristics, the physical and thermal properties of construction materials are also different from those natural materials. Many building materials are very effective at retaining absorbed solar energy and radiating heat into the surrounding environment for hours after sunset. By comparison, rural areas generally cool much more quickly. Therefore, differences in urban and rural cooling rates after sunset often generate the UHI. Additionally, maximum nocturnal UHI development typically occurs on calm, clear nights. Calm winds limit the mixing of urban and rural air, and clear skies promote rapid nocturnal cooling through the loss of longwave radiation.

Another alteration of the energy balance in urban areas involves latent heat exchange. Impervious surfaces combined with a low amount of vegetation in urban areas result in little water being available at the surface to absorb latent heat through evapotranspiration. The result is that much of the excess available net energy goes to sensible heat, often making urban areas warmer than the surrounding, unmodified rural areas.

Urban climatology has experienced tremendous growth since Luke Howard's original study of London's UHI in the early 1800s. Through documenting the UHI of numerous individual cities, scientists better understand the causes of the UHI. We have also learned that cities having similar populations can experience very different UHI characteristics due to the lifestyles of their inhabitants, the geographic setting, and physical characteristics such as land use patterns and choice of building materials. Field-based studies have become increasingly more complex as observational instrumentation has improved. Remotely sensed data have also been used extensively in UHI research to analyze surface temperature patterns and to track land use and land cover changes over time. Data from field research and remote platforms provide information for computer models that has greatly advanced our understanding of UHI dynamics. Despite the vast increase in our knowledge, numerous questions remain about the relationships between UHI and global climate change. Global warming will likely affect cities primarily by altering regional-scale processes such as wind and precipitation patterns. What is far less understood, however, is how urban climates affect larger-scale processes that create uncertainty when trying to model atmosphere processes.

The number of publications about urban climate in both physical science and non-physical-science journals has increased over the past decade. The recognition of urban climate's importance and relevance to other disciplines indicates the health and vitality of the discipline. This is encouraging since urban sustainability efforts must involve numerous scientists, professionals, and stakeholders working together to achieve common goals.

URBAN HIERARCHY

Urban areas exhibit a large range of population sizes—from hamlets to global cities—each having a corresponding economic role within the urban system. Settlements with larger populations that provide more and diverse services are higher up the urban hierarchy. Settlements with smaller populations and a limited number and type of services are further down the urban hierarchy. The size and distribution of urban areas within this system have important implications for economic development.

The urban hierarchy may be illustrated by a pyramid where the smallest settlements (hamlets) are at the bottom of the pyramid and global cities are at the top (Figure 1). Settlements at the bottom of the pyramid have small, rural populations and

Figure 1 Population, settlements, and services in the urban hierarchy

Source: Author.

Figure 2 Urban hierarchy and economic development

Source: Author.

contain a small number and limited variety of economic services within the system. This type of settlement is the most dominant and widespread. Settlements at the top of the pyramid have large, urban populations and contain a large number and wide array of economic services. Usually, there is one settlement at the top of the urban system. As you move up the urban hierarchy, the number of settlements in each category declines as the populations and the number and diversity of services expand. For example, in the United States, the city at the top of the urban hierarchy is New York, which has the country's largest population;

is a major global financial, transportation, and cultural center; and offers a wide variety of social and economic services. Just below this level would be cities such as Los Angeles and Chicago, both of which have large, urban populations and offer numerous retail, financial, medical, education, and cultural services. One step below on the urban hierarchy, we will find cities such as Atlanta, Denver, Seattle, and Miami. Each has large urban populations, but they are smaller in size than the populations of New York City, Chicago, and Los Angeles. They also offer a somewhat smaller number of services. Below this level, we find cities that might be the largest cities within a state and/or state capitals. These cities serve an important economic and administrative role at a statewide or perhaps regional level. Smaller cities that are not state capitals or are not the largest cities within a state are found at the next level. They supply services to a portion or region of the state and have a significantly smaller population. Towns with smaller populations and a smaller array of services depend on nearby cities for more diverse services. Hamlets have small populations and very limited services, such as gas stations, convenience and/or grocery stores, and restaurants.

In the early stages of development and in agriculturally based economic systems, settlements typically are of similar size and are evenly distributed across the landscape (Figure 2, Stage 1). This pattern minimizes transportation costs and competition. Over time, one city or settlement (the core) gains dominance or power over other settlements in the system (Figure 2, Stage 2). This core or primate city may be centrally located compared with the other cities, or it may have an ideal location as a port city for access to water transportation. Primate cities are the largest and most dominant cities within a system of cities. Primate cities have populations many times greater than the second largest and subsequent cities. Usually, primate cities were once centers of much larger systems (e.g., empires). Over time, city systems tend to move toward a rank size distribution (Figure 2, Stage 3).

When a primate city size distribution exists within a system of cities, negative economic consequences can occur. During Stage 1, settlements are of comparable size and economic well-being

Figure 3 Urban hierarchy and degree of primacy

Source: Author.

(Figure 3). As economic development occurs and/or time passes, one city or settlement dominates the region or has a high degree of primacy—now referred to as the core (Stage 2). The core has a high capacity for generating and absorbing change. The core is technology rich and economically rich and depends on inputs from the periphery (the smaller settlements in the systems). Development in the periphery is determined by the core region institutions and tends to be resource rich but economically poor. The periphery is based on outputs to the core. As economic development increases and/or time passes, the system approaches a rank size distribution, and there is a more equitable distribution of wealth across the region (Stage 3).

The world faces comparable challenges of core and periphery regions as globalization occurs. Developed regions (the core) rely on undeveloped regions (the periphery) for resources and labor. Undeveloped regions must deal with rapid population growth in urbanized areas as an agrarian-based populace seeks the promise of higher-paying

factory jobs. As these peripheral regions reach higher levels of economic development, they will become less dependent on the developed world for technology and investment, and the global economic system will likely have a more equitable wealth distribution.

URBANIZATION

The urban world at the dawn of the 21st century has assumed special importance for two principal reasons. First, the world's population has recently crossed the threshold from being more rural to being more urban. In absolute terms and according to UN estimates, this means that of the world's population of approximately 6.8 billion, approximately 3.5 billion people (or 51%) are living in urban settings. To put this notion in historical context, consider that 58 yrs. (years) earlier only 29% of the world population lived in cities. The projection for 2050 is 70%. Second, a dramatic change in the urban hierarchy is taking place as the large cities—variously termed *global cities*, *world cities*, *megacities*, and so on—are beginning to dominate the urban landscape. This entry first reviews the historical development of the urban world, from the earliest settlements in Mesopotamia to the present, and the types of explanations researchers have used to describe this process. Problems in measuring the degree of urbanization are then discussed, including the concept of *urban degree* (the level of a country's urban concentration, expressed in percentage at a point of time). Although urbanization is occurring around the globe, there are significant differences in this process; some of the global trends are noted here. The entry concludes with a look at the future of urbanization.

Along with urbanization, other changes are taking place concomitantly: The rural-urban and interurban mobility of population is accelerating, the traditional rural-urban dichotomy is blurring, and research and technological innovations in economic development and transportation—along with the relaxation of political-institutional barriers—are growing. Consequently, a diversified and unprecedented mix of urban phenomena, urbanization processes, and urban patterns in global and regional scales is emerging, giving rise to complex issues, problems, and prospects. The concentration of urban populations is manifested in many forms and functions—both historically, through cyclical changes (e.g., urbanization, de-urbanization, and re-urbanization), and spatially, from the monocentric, core-oriented settlements to the polycentric, peripherally focused patterns.

Urban fringe, urban cluster, urban sprawl, “rurban,” and extended urban areas are among the terms frequently used to identify and characterize the spatial patterns of the emerging urban landscapes. Urbanization is linked with social and demographic changes such as smaller family sizes, occupational specialization, and increased population densities. Ideally and typically, urbanization is tied with increasing wealth and improved quality of life. While an urbanizing world has the potential to impart extraordinary benefits—including an enhancement of the quality of life—to its citizens, it also faces significant problems that include the degradation of environment and a challenge to urban sustainability. Urbanists seek to analyze these diverse urban issues from a variety of perspectives and scales in order to understand the spatial processes and patterns.

Urban Evolution

Early urban settlements were small but iconic representations or symbols of civilization, extensively written about in a number of regional contexts. Even though the concentration of population in settlements can be traced historically, the evidence of urban origin—the where, when, and how of urban concentrations and their subsequent spread—remains uncertain. Scholarly disagreements on the genesis, traits, settlement patterns, and modes of dispersal of urbanization notwithstanding, we know that urbanization has been a nearly continual process throughout human history. The earliest cities, or urban settlements, first developed approximately 6,000 yrs. ago in Mesopotamia. These were followed by cities developing independently in the Nile Valley in Egypt, the Indus Valley in South Asia, the Yellow or Huang He River valley in China, parts of Africa, and Mesoamerica and South America over the next several millennia. These regions are widely cited as the early “urban hearths.”

Of the theories offered to explain urban origin, four broad theories—hydraulic, economic, military, and religious—provide the dominant views. Briefly, a surplus in agricultural production was a critical notion underlying the hydraulic theory, and the notion of cities as the locations for trade was central to the economic theory. In the military theory, the need for concentration was

attributed to the communal defense, while the role of religious leaders in the organization and control of territories for ensuring the safety and security of community dwellers was the basis of the religious theory. Clearly these explanations are not mutually exclusive.

Historically, urbanization has been linked with the progress of society from agrarian to industrial. Most societies before the 16th century were only marginally urban, as the vast bulk of the populations consisted of peasants and farmers. The mode of agricultural production, extraction of natural resources, and trading activities of urban dwellers had distinctive geographical and locational advantages. Subsequently, the progress of the agrarian economy, increased trade in the 16th century, and the onset of the Industrial Revolution in the 18th century laid the foundation of large-scale urbanization. Cities grew in number and population and became interlinked in trade and commerce.

Urbanization as a global phenomenon accelerated markedly with the advent and expansion of European colonialism. This diffusion of urbanization may be broadly depicted in several phases: The earliest phase grew incrementally and most apparently in Latin America, subsequently appearing in South Asia, Southeast Asia, and Africa. Other parts of Asia, such as China, were affected too, though later and not to the same degree. This first phase, lasting until the mid 1800s, was rooted in city-based mercantile colonial activities. During this period, city growth occurred mostly in colonial trading centers.

A second, industrial colonial phase was evident from the mid 1800s through the 1920s. During this phase, urbanization was increasingly tied to the extraction of raw materials for industrial activities and for growing food consumed in the rapidly expanding industrial centers. States were more directly involved in territorial control of their colonies. Colonial urbanization became more complex and more pervasive. Cities grew rapidly, became denser and increasingly segregated, and came to bear the hallmarks of European colonial planning.

The emergence of diversified urban economies and the development of a variety of transportation modes in the 19th century provided the stimulus for urbanization to accelerate, while

distinctive patterns of urbanization became evident during the second half of the 20th century, especially during the post-World War II period. Several factors can be attributed to this distinctive pattern. First, many of the so-called less developed countries gained independence from colonial rule and initiated socioeconomic developmental planning emphasizing large-scale industrialization. Second, some of the more developed industrial countries shifted their industrial base from traditional manufacturing to a wide range of tertiary activities. This shift altered the location of activities by prompting regional redistributions of population within countries while spreading industries to new sites outside the core cities and countries. Third, the revolutions in finance, trade, and commercial activities involving both the developed and the developing countries, particularly during the past 25 yrs., gave rise to the process of globalization, which is intrinsically linked to the accelerated growth and development of many larger cities. One prominent outcome of the globalization process is seen in the emergence of the current global city or world city.

Throughout world history, urbanization, industrialization, and societal changes have been closely interrelated. Two key factors, broadly speaking, have shaped the pattern of urbanization over the centuries: the demographic (population base and growth rates) and the economic (resource base, growth rates, and development), making the socioeconomic development path key to understanding urbanization. This intricate relationship makes it imperative to understand, measure, and monitor urbanization, primarily by means of assessing the urban concentrations of population in space and over time.

Measuring Urbanization

In general, urbanization is described as the process of concentration of a population in space designated as urban—a process that encompasses the migration of populations from rural to urban areas, a natural increase in the urban population, and a reclassification of rural areas to urban. Although the idea of spatial concentrations of population might appear to be simple, it is well recognized that a variety of its correlates manifest

themselves in urban space, reflecting the complexities of the process. Virtually all the countries of the world have designated their urban places or areas, although the conceptual definition of the term *urban* remains variable. Broadly, the following are among the key criteria that have general global acceptance:

- A minimum threshold of population size, built-up area, or density
- Occupational traits of the labor force (primarily nonagricultural)
- Administrative status
- Spatial structure and organizational pattern

In spite of the general agreement on the key criteria, the study of urbanization is fraught with two problems, namely, that the urban concept is not uniformly defined across the globe and that the data on the criteria for urbanization lack uniform definition, stringency, accuracy, or availability. These problems make it difficult to adequately assess and compare the urban status or patterns of individual countries or regions, not to mention the difficulties involving intracountry or cross-country comparability. Traditionally, easily computable demographic data, such as a minimum threshold of population size, are used for determining the urban status of a designated place. This simple approach reflects one of the many urban traits that arise out of population concentration. Wide variations in urban concentrations are apparent across nations, usually related to the countries' levels of development and industrialization. In this respect, measurement of urbanization becomes a key indicator in assessing the developmental status.

The change in the degree of urbanization (urban degree) can be measured in two ways: (1) urban growth—the difference in the level over a period of time and (2) the relative difference between urban and rural growth rates. If the urban growth rate exceeds the rural growth rate over a specified time period, an urbanizing process sets in, indicating change in the societal status of the country. The measure of concentration and change in a population, as noted in its urban degree, growth, and urban-rural differentials, is related to a host of underlying demographics (e.g., birth rates, death rates), economic

(e.g., migration of labor force), and/or administrative (e.g., urban designation policy) factors.

Global Trends: An Overview

The difficulty in generalizing about global urbanization primarily arises from the complex geographies of countries and regions. First, the geographic patterns of the level of urbanization vary substantially across the globe. By world region, the world's most urbanized areas are North America (the United States and Canada; 81%), Latin America (78%), Europe (72%), and Oceania (71%). Less urbanized areas are Africa (39%) and Asia (41%). Given their demographic magnitude, it is wise to single out the urbanization levels of China (47%) and India (29%). Notable countries at the extremes are Singapore (100%) and Uganda (13%). Next, the pattern of change across the developed and less developed regions, both in the number of urban populations and in the rate of urbanization, are noticeably uneven (Figure 1). Irrespective of their level of urbanization, during the 25 yrs. following World War II, the urban population steadily increased in both the developed countries and the less developed countries. However, during the next 25 yrs. (1975–2000) both the size and the growth rates of the urban population in the less developed countries significantly exceeded the same in the more developed countries.

The urban structure, depicting the proportion of population distributed in a variety of size groups of places within given geographical and/or administrative territorial boundaries, can indicate important attributes of spatial development as observed in many regions in less developed countries. During the period from 1975 to 2000 (Table 1), the pattern of change in three selected hierarchical size groups of urban population showed a steady rise in the number of urban settlements in the smallest (<1 million population) size group, while they declined in their share of the total urban population. For the intermediate (1–5 million) and the largest (>5 million) size groups, the number of settlements increased, while their proportion of total urban population either increased or remained steady during these years. The structural patterns did not show much variation between the more developed countries and the less developed countries. However, compared

Note: MDRs = more developed regions, LDRs = less developed regions.

with the smallest (<1 million) size group, a rather dramatic growth in the number of settlements for the two larger-size classes in the less developed countries depicts significant changes in the urban system (Table 1).

The emergence of megacities—those with 10 million or more people—marks a milestone in the 20th-century urbanization of the less developed countries. Out of a total of 19, there were only 5 megacities in the developed regions in 2007 (Table 2). It is estimated that by the year 2025, only one more city will be added to the megacity list in the developed region, while the rest, accounting for nearly 80% of the total number of cities, will be in the less developed countries. Over the past two decades, megacities in the less developed countries have experienced significant growth. Some, such as Dhaka in Bangladesh and New Delhi in India, recorded a huge increase of 11.3 million and 11.5 million people, respectively, during the period from 1975 to 2007. The average population of the world's largest 100 cities now stands at more than 7 million, compared with only 700,000 in 1900. The observed trends are attributed, broadly, to the forces generated from

within (e.g., development policies) and/or outside (e.g., economic globalization) the more developed countries and the less developed countries.

The Urban Future

Urbanization is a universal process. No matter how its evolutionary path is traced or interpreted, the certainty of its steady pace can hardly be disputed. Much social progress and development and economic prosperities are derived from urbanization. The continuity of the pattern of growth and pace, however, also clearly indicated the vulnerability of the urban environment. The basic issue for the future, then, is simple: How should the urban world grow?

While discussing the pros and cons of urbanization in the context of the global urban revolution, there are two major differing views on the state of urbanization. The “urban optimists” are motivated by the notion that the societal benefits of urbanization generate an overall improvement in the quality of life of the individuals as well as in the developmental levels of nations. The “urban pessimists,” on the other hand, worry

Urban Agglomeration	Population in Millions

about the adverse effects of urbanization, especially in the context of the developing countries, where socioeconomic unrest and urban pathologies such as poverty and slums continue to plague society. People across the globe perhaps see their individual and collective urban futures somewhere along the continuum.

To optimize the benefits of urbanization for societal development while minimizing, or at least coping with, its adverse consequences, it is imperative that research be focused on the global, national, and regional or local scales to understand the divergent paths of the complex urbanization phenomenon. In charting the future course of urbanization, the needs and wants of the people

for a desirable urban living environment in a variety of contexts must be incorporated. Just as it is essential that the stakeholders—the citizens, the private and the public bodies—participate in envisioning the urban culture for shaping the future, it is equally crucial to collect, store, and distribute accurate and comparable urban data for ongoing research that would serve as the foundation for effective planning strategies and policies.

URBAN LAND USE

Cities across the world are complex mosaics of economic, social, political, and recreational land uses. How and where these land use activities are organizationally patterned reflect not only a city's primary function (e.g., an "economic engine" in an industrial economy or a "cultural/administrative" center in an agrarian economy) but also at least two other overarching forces—accessibility and territoriality/congregation/segregation. In general, the utility of a designated place or location within a city is defined by its potential usefulness, which, in turn, is often a function of its accessibility. Activities that tend to be land intensive have a propensity for high levels of interaction and serve a necessary and functional purpose that requires accessible locations. Alternatively, low-accessible locations are occupied by those land use activities that are characteristically land extensive (activities that require the use of large tracts of land) and functionally peripheral and independent (Figure 1).

Figure 1 Economic competition, accessibility, and the resultant urban land use patterns in relationship to the central business district (CBD)

Source: Author.

At the same time, land use activities are often organized in clearly demarcated geographic *territories* so as to define and preserve “group” membership and identity. Typically, this involves the use of both inclusionary and exclusionary practices in an effort to create homogeneous groupings by housing, retail/commercial establishments, professional services, and industry. Of particular significance is the occurrence of *congregation*—a voluntary territorial and residential clustering of specific groups of people (i.e., language, religion, race, lifestyle, among others) that engenders a sense of place unity as defined by a common electoral power base, a system of reciprocal support, and cultural preservation. However, there also exists an involuntary form of congregation (*segregation*) that results in territorial and residential clustering involving discrimination and the spatial separation of specific groups of people. In this way, both accessibility and territoriality/congregation/segregation are important place-defining forces that shape the internal structure of cities worldwide and their urban land use patterns. This entry discusses four urban land use models: (1) the concentric zone model, (2) the sector model, (3) the multiple-nuclei model, and (4) the peripheral model, as well as the application of these models.

Urban Land Use Models

Whereas economic competition, accessibility, and the propensity toward social and ethnic discrimination/segregation/congregation are evidenced in many of the cities across the globe, the resultant urban land use varies considerably due to the influences of culture, history, and particularly the functional roles cities have played in the world economy. Since the 1920s, geographers, sociologists, and economists have attempted to identify and examine the ever-evolving geographic placement of people, economic activities, and administrative functions in cities. Within the North American context, four models describing the internal structure of cities have been developed: (1) the concentric zone model, developed by Ernest W. Burgess in 1923; (2) the sector model, developed by Homer Hoyt in 1939; (3) the multiple-nuclei model, developed by Chauncy Harris and Edward Ullman in 1945 (Figures 2A, B, and

C); and (4) the peripheral model, developed by Truman Hartshorn and Peter Muller in 1989 (Figure 3).

Traditionally, the city’s center, commonly known as the central business district, or CBD, has served as the principal “hub” for retail, office, and significant administrative/institutional land use activities. In particular, the CBD has not only contained the highest density of all these land use activities but has also been positioned at the nodal point of transportation systems and is visually characterized by an impressive vertical skyline. Typically, the CBD is surrounded by a zone of mixed land uses, including older residential neighborhoods, small factories, warehousing, and multifamily residential complexes, and is often collectively referred to as an urban land use “zone in transition.” Geographically, beyond this zone is a mosaic of residential neighborhoods and suburban territories of various age, social, and ethnic compositions.

Concentric Zone Model

The concentric zone model was the first attempt to explain the distribution of different social groups within cities. Fueled by streams of migrants and immigrants from diverse cultural backgrounds to the North American industrial cities throughout the late 1800s and early 1900s, residential territories of congregation were established to provide a sense of security, communication, and familiarity. On average, these original ethnic communities persisted over one to three generations, after which an increasing number of individuals from these groups were able to obtain better employment and therefore relocated to newer, higher-income housing that was being built at greater distances from the CBD. In this way, the concentric zone model proposed a continual outward expansion of the city (in the form of concentric rings or zones), with the development of ever newer, more spacious and expensive residential neighborhoods (Figure 2A).

Sector Model

In 1939, a second urban land use model was developed by H. Hoyt. Because the key component influencing the geographic placement of land use activities in this model was accessibility,

Figure 2 The three urban land use models: concentric zonal, sector, and multiple nuclei

Source: Author.

Hoyt argued that cities developed in a series of sectors (aligned along transportation “corridors”), not concentric rings (Figure 2B). As a city expanded geographically outward radial, as opposed to circumferential, transportation systems were built (e.g., suburban commuter roads and streetcar and elevated rail lines) to facilitate and channelize growth. And due to economic competition and the compelling demand for accessibility, land use activities located and geographically sorted themselves into clusters or sectors that were congruent with the transportation arteries radiating outward from the CBD. In this way, Hoyt suggested that high-rent residential areas grew outward from the CBD, along major transportation routes, surrounded by middle-income housing, and low-income housing settled in districts adjacent to the CBD near industry. Finally, the dynamism of the sector model is characterized by a “filtering-down process,” as older residential neighborhoods were abandoned by the outward movement of their original high-income occupants and were replaced by households of the next lower-income strata.

Multiple-Nuclei/Peripheral Model

In contrast to the concentric zone and sector models, the multiple-nuclei model views urban land use in cities as being shaped by several nodes of growth, as opposed to the single-CBD assumption (Figure 2C). In 1945, Harris and Ullman suggested that different land use activities have uniquely specific locational requirements; for example, retailing needs accessibility, heavy manufacturing relies on horizontal production spaces near railroads, port functions are best served by waterfront activities, and other nodes, including universities, airports, and parks, may serve as the focal point for other types of land use activities. And basically, both territorial segmentation and segregation were hallmark characteristics for understanding the resultant spatial pattern of urban areas.

While these three urban land use models are somewhat dated for explaining present-day urban land use patterns, they nevertheless continue to provide a historical baseline to the structural underpinnings of land use in contemporary metropolitan complexes. As an extension, Hartshorn

and Muller have proposed a peripheral land use model that accounted for the pervasive suburbanization of a multiplicity of CBD functions between 1970 and 1990 (Figure 3).

The peripheral model focuses on the circumferential outer beltway that has redefined the role of suburban nodes, not by their relationship with the traditional CBD but rather with other outlying suburban nodes. Contained within the peripheral model is the notion that households are highly segregated into relatively homogeneous suburban territories, whereby suburban nodes are highly developed and self-supporting employment, retail, and recreation centers. Finally, peripheral models legitimize the occurrence of exurbanization—a “residential appendage”—as the outermost land use activity connected to an urban area.

Application of Models

None of the four models individually and completely explain urban land use patterns. Partly due to their simplistic assumptions as well as the time period in which they were developed, the models do not encompass all the changing forces that geographically shape today’s urban communities. Nevertheless, the four urban land use models collectively provide the structural basis for understanding the social, economic, and political geographies of the contemporary city. While the four models may be particularly useful to describe urban land use patterns in North American cities, adjustments are needed for their application in both European and less developed country (LDC) contexts.

In particular, wealthier people in European cities not only cluster along specific sectors extending outward from the CBD but more prominently occupy places of residence in and adjacent to the CBD. Historical preservation combined with the numerous cultural amenities found in European CBDs, along with high transportation costs (fuel), make living and functioning in or near the CBD in high demand. As such, the poorer European urbanites tend to dominate the outer “suburban” tracts of land. Moreover, there exists an important distinction between Western and Eastern European cities. Namely, Western European cities and their resultant land use patterns are deeply

Figure 3 The peripheral urban land use model

Source: Author.

rooted in their medieval origins, Renaissance restructuring, and level of industrial capitalism. Their geographic compactness, high population densities, and pervasive “apartment”-style residences have fostered the continued reliance on public forms of transportation. Cities in Western Europe often combine places of residence with places of employment; for example, retail/business establishments occupy street-level space, while subsequent upper levels are occupied by households for living space. In many of these cities, the historic core is gentrified, where the middle-income groups, the elderly skilled artisans,

and the young entrepreneurs share space and intermingle with preserved historical buildings, monuments, and tourist attractions.

In contrast, Eastern European cities and their resultant land use patterns reflect a different ideological base—centrally administered planning principles. In particular, explicit segregated land use, “intra” neighborhood equality and autonomy, and restrictions on the geographical size of a city were adopted during the communist period, from 1945 to 1990. While none of these objectives ever became fully implemented, they have served as the cornerstones for the geographic

layout of Eastern European cities. Slowly but steadily, as the former Eastern Bloc countries, along with the former Soviet Socialist Republics that are now part of Eastern Europe, increasingly incorporate market principles of land allocation, the land use pattern of Eastern European cities may begin to resemble that of their western counterparts.

By comparison, the fastest-growing cities and the most rapidly growing populations are found in the developing world. Despite the variety of urban structure that abounds in culturally diverse regions such as Latin America, the Middle East, and Africa, there exist at least three common planning principles that underlie their urban land use. First, the lowest-income individuals have and continue to increasingly situate themselves in the outlying areas of the city, away from city services, often occupying the land illegally and forming squatter settlements. Second, there is an absence of adequate urban infrastructure to support the growing population—sanitation, drinking water, roads, electricity, and so on. Third, many of these cities have a colonial heritage that, over an extended period of time, left indelible architectural, religious, political, and cultural imprints on the geography of the city. In much of the developing world, urbanization is driven by massive rural-to-urban migration. In short, urban land use in less developed countries is primarily a culmination of historical origin, colonial imprint, and functional role within its current cultural setting.

Conclusion

Urban land use of cities across the world, whether in North America, Europe, or the developing world, is reflective of underlying antecedents for the design and planning of urban space. Whether land use is based on “grid systems” (the remnants of Greek and Roman settlements), position of power or celebrated glory (e.g., the Renaissance), religious edifices (e.g., the mosque, cathedral), military ordinance, or cities that should be designed and function like “machines” (e.g., the modern movement and industrial capitalism), geographical principles play a significant role in all urban landscapes.

URBAN METABOLISM

The concept of urban metabolism provides a framework for examining natural resource flows and use in urban areas. Urban metabolism studies draw an analogy with the metabolic requirements and processes of an organism. Like an organism, a city requires water, energy, food, and other resources to fuel, grow, and reproduce itself. It also produces wastes and residuals that must be disposed of with minimal hazard. Urban metabolism studies can be used to provide insight into the sustainability of the relationships between a city and its supporting physical environments and have recently begun to include social and economic relationships as well.

The first formal urban metabolism study was prepared in 1965 by Abel Wolman for a hypothetical North American city of 1 million inhabitants to highlight key urban environmental issues of modern industrialized cities: the

Material Flow		10 ⁶ Tons/Year			Kilograms Capita ⁻¹ Year ⁻¹		
		1971	1997	% Change	1971	1997	% Change
Inputs	Food	2.4	5.0	+108	570	680	+20
	Fossil fuel	4.0	13.0	+225	1,000	2,000	+100

provision of a safe and adequate urban water supply, the effective disposal of sewage, and the control of air pollution. Since then, approximately 10 urban metabolism studies of actual cities have been conducted, including Hong Kong, Vienna, Toronto, Tokyo, London, and Sydney. Analysis using urban metabolism as a framework metaphor typically takes the form of a material flow analysis, where researchers take stock of the inputs, storage, transformation, and output of different materials and their residuals across a defined urban system and over time. While some studies look specifically at the flow of a single material such as water or nitrogen, most provide a comprehensive accounting of inputs and wastes.

Taking stock of material flows across an urban system and over time helps draw attention to the need to examine the systemwide impacts of the consumption of natural resources and provides valuable information for decision making and planning for the future of cities. An urban metabolism study may reveal inefficiencies in resource use, opportunities for policy intervention to slow or prevent the exhaustion of resource supplies, and the sources of potential problems from the buildup of potentially hazardous materials and emissions within the urban system and its surrounding environment.

Urban Metabolism as Indicator of Sustainability

Different indicators describing the metabolic flow of resources can be used to draw conclusions about the sustainability of a city's urban metabolism and therefore of the city itself. These include the magnitude of and changes in the total and per capita resource use and waste generation and the degree of circularity in resource use.

Most urban metabolism studies indicate that in general the magnitude of the per capita resource use in cities is large and increasing. For example, a comparison of the comprehensive studies of the urban metabolism of Hong Kong in 1971 and 1997 (Table 1) demonstrates increases of 20%, 100%, and 280% in the per capita consumption of food, fossil fuels, and construction materials, respectively. In addition to increased resource use, Hong Kong's total waste and residual outputs of municipal solid waste, carbon dioxide (CO₂), and sewage discharges have also risen by 245%, 250%, and 153%, but per capita air pollutants emissions have decreased by 23%. A review of urban metabolism studies from eight metropolitan regions across five continents suggests that the trend of increasing total and per capita urban metabolisms is prevalent worldwide, fueled in part by increasing urbanization and material wealth.

Figure 1 Linear and circular urban metabolism

Source: Girardet, H. (1992). *The GAIA atlas of cities: New directions for sustainable urban living* (pp. 22–23). London: Gaia Books.

Herbert Girardet, a long-time scholar of the urban metabolism of cities, highlights the shape of a city's urban metabolism as another key indicator of sustainability (Figure 1). A city's urban

metabolism may be linear, where input is unrelated to output. A city has a linear urban metabolism when it acquires, concentrates, and consumes ecosystem resources and disposes of its

waste products in a manner such that they cannot be reused or may potentially cause harm to other systems or the city itself. In most cities, the use of fossil fuels is a prime example of a linear urban metabolic process. Fossil fuel resources from beyond urban system boundaries are stored and then consumed as sources of energy, and the waste products of heat such as particulate emissions, nitrogen oxides (NO_x), sulfur dioxide (SO_2), CO_2 , and other greenhouse gases are released and contribute to the creation of the urban heat island effect, climate change, acid rain, and air pollution.

On the other hand, a city's metabolism may be circular, whereby it is able to reuse or recycle its waste products or return them as a source of inputs for other systems. In many North American and European cities, the flow of food and the embodied organic matter, nutrients, and energy within is becoming a more circular urban metabolic process. Food products are brought into or grown within the urban system and consumed by its inhabitants. The waste products of garbage and sewage are increasingly collected and treated by the city. In some cities, innovative waste management practices are used to produce compost and other soil amendments from food wastes that can be reused as inputs for agriculture and horticulture or to capture methane and heat to serve as new sources of energy. A narrowly focused study of food nitrogen flows in Toronto, Canada, from 1990 to 2004, suggests that the degree of circularity in the urban nitrogen metabolism is between 2.3% and 4.7%. This circularity appears quite low, given the number of municipal programs aimed at collecting and composting household food wastes. The accounting revealed that major sources of the linearity of the nitrogen metabolism were in sewage treatment and commercial food waste disposal. This finding emphasizes the ability of an urban metabolism study to identify processes at which to target interventions to increase the sustainability of a city's relationship with its surrounding environment.

Factors Influencing City Metabolism

There are several factors that influence the magnitude and shape of the urban metabolism of

cities. The natural and physical built form characteristics of an urban area, such as climate and surface and groundwater resources, as well as urban form and transportation technology, are key determinants of total and per capita energy and water use. For example, a low-density sprawling city in an interior continental climate is likely to have a larger metabolic energy requirement for transportation, heating and cooling, and water distribution than a compact city of the same population size in a temperate climate.

Municipal policies and practices such as building codes and waste and water management technology, as well as urban residents' attitudes and behavior, will also influence a city's urban metabolism, in terms of both its magnitude and its degree of circularity. For example, the degree of circularity of a city's urban metabolism can be increased through composting and recycling, grey water separation and reuse, and district heating and cogeneration facilities. The success of municipal policies aimed at reducing the magnitude of urban metabolism will require targeting inefficiencies in resource use and reuse and significant participation by urban residents, who also must be supported by appropriate changes in infrastructure and urban form. By taking stock of resource flows, urban metabolism studies can help identify both current and future trends in resource use and track progress toward greater sustainability between cities and their surrounding environments.

URBAN PLANNING AND GEOGRAPHY

Although the world population has historically been rural, there are now more people in urban areas than in the rural hinterlands for the first time in history. According to UN estimates, in 2010 more than 3.5 billion people (50.6%) will inhabit urban centers around the world, with the highest concentration of large urban centers in Asia (Table 1, Figure 1). Typical of this concentration is the metropolitan complex of Tokyo and Yokohama, Japan, with the largest urban population of approximately 36 million people (Figure 2). The growing urban areas need to provide for citizens' demands for housing, employment, transportation, infrastructure, and the vast array of services and facilities. To meet these demands, it is essential to understand the environmental, social, economic, and political characteristics of the ever-growing urban realm. Urban geography has contributed significantly to this knowledge and continues to expand its role by providing theoretical, technological, and analytical advancements to assist in this effort. Correspondingly, the integration of this knowledge and its implementation into strategies, policies, and programs to meet the needs of the urban population is a task planners have undertaken. The implementation of their plans is a key component to ensure the health, safety, and well-being of urban citizens. The spatial dynamics of the urban area and its growth management create the interaction between urban geography and urban planning and are the focus of this discussion.

Year	Total	Urban	%

Urban Geography

The description and analysis of urban areas has been a subject of study for geographers since the earliest settlements. The distribution and location of urban centers and the factors that influence their spatial patterns provide for the understanding of urban development and, in some cases, their demise. Figure 3 illustrates the multidimensional approach that geography has taken in the study of urban areas. There are four dimensions to the geographical analysis of urban areas: (1) the spatial, (2) thematic, (3) analytic, and (4) chronological. The overall thrust of this research has been through a spatial dimension or lens focusing on a thematic factor or some combination of factors, such as the environmental, social, economic, or political characteristics. The spatial lens changes with scale, so that by zooming in a theme can be investigated at the local level or microscale—a neighborhood or a smaller portion of the city—and by zooming out the global interrelationships (macroscale) between cities or metropolitan areas can be examined. The spatial dimension establishes the context in which the theme can be described and analyzed. Urban areas consist of only a tiny portion of Earth's land surface (.5%); however, they are home to currently more than 50% of the population. Urban geography has to be able to analyze this landscape at various scales because of the interrelationships and connections within an urban area and between urban areas across the globe.

Figure 1 World total and urban population, 1990–2030

Source: UN Department of Economic and Social Affairs, 2008.

The thematic dimension of urban research provides the elements of an urban area that are linked together to establish its character. The city is a system either within its own area or as a part of the interconnection between cities, and it is imperative to know the elements of the city or cities to understand how the system works together. The general environmental, social, economic, and political dimensions are the broad characteristics of any city. However, there are many subthemes that are more specific; for example, the social dimension can be subdivided into families, race, ethnicity, or medical history. The number of subthemes can be limitless depending on the specificity of the researchers and their characteristic interest. This notion is made more complex by the investigation

of multiple subthemes spanning several major elements. The spatial distribution of environmental quality and its impacts on health and living conditions for the underprivileged of a specific ethnic background are an illustration of this point. Thus, many different subthemes of several elements can be examined at different spatial scales.

Urban research's analytical dimension has four main components: form, function, process, and structure. Each component represents a different aspect of the urban area that broadens our understanding of the city system or system of cities. The form is generally the arrangement of the urban elements or subthemes and is represented by their spatial distribution at a local, regional, national, or global scale. The functional component of an

Figure 2 Major world cities. Most of the world's large cities and most urban growth are found in economically developing countries.

Source: Author.

investigation explores the purpose, role, or meaning that the subtheme has within the city system or system of cities. A city may have an economic base on which to focus, and the investigation may be concerned with what role that city has within the broader economy of the region, nation, or international system. The process component of this dimension is examined using many different methods based on the subtheme being researched. The importance of process is that it reveals the interrelationships, linkages, and connections between the subthemes. The strengths or weaknesses can be examined, which can provide the cause-and-effect relationships between the social, economic, and environmental issues within the urban area. Finally, the structural component of the analytical dimension is the foundation on which the urban form, functions, and processes are built. The structure provides the rules of urban operation, whether it is the capitalist-driven international system of manufacturing cities or the socially conscious neighborhood that has formed a cooperative for housing, employment, and food distribution. The structure

presents the assumptions that are the bases on which the urban system operates. Without knowing the underlying rules or assumptions, it is difficult to understand the relationships, linkages, or connections between the subthemes. Urban geography investigates urban areas using all the different analytical components for a better understanding of the overall city system or system of cities depending on the spatial scale and the intent of the research undertaken.

The final dimension of urban geography is the chronological. There are four approaches that urban geography has taken in this dimension—(1) historic time, (2) a progression or sequence in time, (3) the present time, and (4) the future or predictive time. The historic time approach is an investigation of an urban area at a specific date or time span in the past. A study of the spatial distribution of Spanish Moorish cities in the 12th century and their function for western expansion would be an example. The intent is to understand a component of the analytical dimension using the thematic dimension. The progression or

Figure 3 Multiple dimensions of urban geography

Source: Author.

sequence-in-time approach to historic urban geography examines the change over time within or between urban areas. This approach may use several of the analytical components to investigate a specific urban area in order to understand what processes create a change in form or how structural changes manifest themselves in the urban area. The majority of urban geography, however, is concerned with the present or current time dimension. The intent is to know the current factors, situations, and results of contemporary urban society. Data and information are collected and analyzed with the purpose of strengthening the relevance of solving today's city issues. Finally, the ability to project into the future through analytical and scenario-based computer programs

allows urban geography to envision what may be the result of contemporary urban activities based on structural assumptions. The ability to model future urban areas may have great significance to world society because the United Nations has predicted that the proportion of the world population in urban areas will increase to 80% by 2050, totaling almost 7.4 billion people.

Planning

Urban areas are generally the result of the landscape's characteristics, social and economic activities, and infrastructure of historic urban development. To meet the ever-expanding needs of the urban population, urban planners and

engineers incorporate modern design and technologies into this historic context. However, they do not work alone; multiple agencies work together to maintain existing facilities and services and identify, predict, and construct new facilities and expand services for the future population. Local and regional planners apply either reactionary or visionary planning tools and techniques to construct strategies, policies, and programs designed to address the identified issues and needs. The local planner generally works with citizens at the neighborhood or community level to identify problems and examine different policy options to solve both immediate and long-term problems. Citywide or regional planners address the broader issues, incorporating input from multiple areas of the city or its jurisdictions, with the same purpose of examining different strategy and policy options to solve these broad issues and meet the citizens' needs. Urban planners examine the urban form, functions, processes, and structures that combine to create the urban area. The different scales of the problems are addressed by different levels of planning, local to regional, with coordinated and cooperative goals to assist in making the city a better place for living, working, and recreation.

Planning entails different approaches and techniques based on the scale of the project. Generally, urban plans will be comprehensive in their approach or will address a specific topic or urban area. The most common is the comprehensive plan that is constructed to identify the overall community vision and develop goals, objectives, and policies for specific topics, for example, environmental protection, land use, economic development, and so on, to lead the community in the direction of their choice. The plan then becomes a guiding document for decision makers because it has identified and prioritized those topics that the community believes are important. Policies and programs are then implemented to obtain the goals and objectives stated in the plan. Another type of plan is a more detailed analysis of a topic area, for example, environmental protection or neighborhood, and this type of plan establishes more specific sets of strategies, programs, and policies that will be implemented to reach the plan's stated goals and objectives. Because they are more specific in either the topic or the scale of

the plan, different techniques for obtaining data and information along with the analysis are employed by the planners to reflect the finer detail of the plan. Both types of plans, however, have the same purpose: to address the issues of the urban community and provide for the citizens' health, safety, and welfare.

Integration

Urban geography and planning are not separate activities; they each rely on the results of the other to create a livable, sustainable urban environment. The incorporation of the different urban geography dimensions into the analysis of urban issues is part of the task of the planner, so that they can determine the most feasible strategies, programs, and policies to address the problems. In particular, geographic information systems (GIS) have been of particular usefulness to both activities because they are multidimensional and have the capability to predict future results or scenarios based on differing sets of assumptions. A GIS is designed to analyze georeferenced data at different spatial scales and the complexities of multivariate analysis. GIS have been used at the neighborhood level to organize and provide current information to community organizers for housing and employment problems. At the city level, a GIS is used daily for transportation routing, maintenance, and problem solving. Even at the global scale, GIS is assisting with issues of global warming and pollution control by monitoring environmental conditions and simultaneously evaluating alternative strategies to mitigate the impacts of the increasing urban population. Urban geography and planning provide the theory, applications, and policies that are needed to address the ever-expanding urban world.

URBAN POLICY

Urban policy refers, broadly, to the numerous ways in which national or federal governments implement programs that affect the nature of cities, including modes and priorities of financing municipalities, strategic planning to stimulate urban economic growth, attempts to combat uneven regional development or encourage cooperation among local governments, control over negative externalities such as destruction of the natural environment, targeted subsidies for specific problems (e.g., homelessness), and political restrictions on the autonomy of the local state. As such, urban policy is closely related—but not identical—to urban and regional planning efforts. There is typically no single national urban policy, but aggregations of many different policies, some of which may work at cross-purposes, with varying effects over space and time. Because the capitalist city is not simply the product of market forces, but also of the state, urban policy plays a critically important role in shaping urban space and the quality of life within it.

Most “urban” policies are not specifically called urban; rather, they affect cities indirectly, such as when they address issues such as infrastructure, transportation, urban labor and housing markets, environmental problems (e.g., water supplies, air pollution), energy use and availability, and so forth. Policies aimed at specific economic sectors, such as protectionism for manufacturing firms,

have uneven urban impacts; similarly, immigration controls differentially affect the supply of labor in urban space. Indeed, virtually all government policies have implicit, if not explicit, urban consequences, such as tax laws, land use controls, and anti-poverty programs.

Urban policy is both deeply political and geographical in nature. Far from being politically neutral, urban policies reflect the interests of multiple constituencies and stake-holders, including corporate interests, different social classes, various groups in civil society, and different factions within the state. Although urban policy often caters to hegemonic interests, it is important to view it as a contested arena in which different political interests and discourses jockey for influence. Additionally, because urban policy varies among and within countries, because it shapes urban space in different ways, urban policy is also profoundly spatial in nature.

This entry begins by noting variations in urban policy among countries; next, it briefly summarizes Keynesian urban policy that dominated in the early to mid 20th century; then, it focuses on neoliberalism and its impacts concerning how governments treated urban areas. Next, the entry discusses the implications of these trends for local planning efforts. It concludes with comments concerning urban policy in the developing world.

National Urban Policy Differences

Urban policies vary widely in time and among countries, depending on the global political and economic system, the structure and health of the national economy, their respective degrees of urbanization, national political dynamics (e.g., unitary vs. federal government structures), the relative degree of political autonomy enjoyed by local governments, modes of tax collection and disbursement of public moneys, national and local administrative priorities, the nature and severity of social problems, and popular historical and cultural climates that facilitate or inhibit government intervention.

Compared to Europe, Japan, or Canada, the political culture in the United States is markedly more favorably disposed to presumptions about the primacy and efficacy of the “free market” and exhibits a widespread mistrust of government

intervention. As a result, with most governance effectuated at the local level, urban policy in the United States has always been relatively anemic compared to European states. In the United States, the bulk of tax revenues are generated and most public services are provided at the state and local levels rather than the federal one, and the country lacks national planning systems regulating land use, population, or other policy measures. Thus, despite the importance of the federal government in financing many local measures, American urban policy tends to be relatively ineffectual. In Canada, Germany, and the United States, provincial, Länder, and state governments, respectively, play important policy roles, a dimension lacking in Britain and many European countries.

European urban policy, in contrast, is typified by significantly stronger national governments, stricter controls over local policy implementation and land use (e.g., historic preservation), and more widespread popular acceptance of such measures. In France, for example, a long tradition of a powerful national government has tended to resist many recent initiatives toward privatization and deregulation common in the United States or Britain. In contrast to the United States, where corporate interests tend to figure prominently in federal and local policies regarding urban space, European policy measures tend to leave more room for the interests of the working class and popular political will. Uneven development and attempts to alleviate it via regional development strategies have long been more important to European countries than in the United States. There are wide variations among European states: Germany, for example, retains a much stronger tradition of social democracy and centralized policy making than does Britain, which more closely resembles the United States in this regard. Sweden and Greece both lack explicit national urban policies; however, while Sweden allows almost complete local autonomy for its cities, such independence is almost nonexistent in Greece. However, recent initiatives of the European Union have fostered a gradual, if halting, policy convergence among countries.

In Japan, urban policy has long focused on attempting to encourage growth outside of the major metropolitan regions, in which the bulk of the nation's population and productive capacity are concentrated. Traditional policy measures in

Japan were exceptionally heavy handed, dictated by fiat from the national government to local ones with little opportunity for feedback. Recent economic stagnation and gradual population decline have forced a more relaxed departure from this rigid top-down system of governance. Lax regulatory controls are often widely perceived as diminishing the aesthetic quality of Japanese urban landscapes, and recent legislation has encouraged local governments to address this issue.

Keynesian Urban Policy

As the economies of many Western countries became focused on Fordist mass production in the late 19th and early 20th centuries, urban policy began to assume a focus on regulating growth and minimizing social inequalities that could prove to be disruptive. Although its origins may be traced back to the Progressive Era at the turn of the 20th century, Keynesian urban policy began to be implemented emphatically in the Western world during the Great Depression of the 1930s as a result of that crisis. In part, this set of initiatives included attempts to stimulate aggregate demand, particularly in sectors such as housing. For example, in the United States, the Federal Home Loan Bank was erected in 1932 to subsidize credit for mortgage providers. In 1934, the National Housing Act established the Federal Housing Administration, through which the federal government insured numerous mortgages. It also initiated the policy that allowed deductions of interest paid on mortgages from federal income tax, which subsidized the middle class, encouraged suburban expansion, and persists to this day. Public housing projects also emerged, eventually comprising 20% of the British housing stock but only 2% of that in the United States, where it was pioneered under the Public Works Administration but later passed to the U.S. Housing Authority. In Britain, local authority housing programs witnessed the construction of millions of working class housing units, a system extended by the Building Societies of the late 20th century. Other measures include national government attempts to assist fiscally distressed local governments, stimulation of employment, and massive infrastructure expenditures, all of which powerfully affected urban spaces and social life.

Keynesian urban policies in Western Europe, the United States, Canada, and elsewhere persisted well after World War II throughout the long post-war boom, although they assumed different forms in different countries. Many governments provided assistance to veterans in the purchase of houses, and their policies amplified a long-standing trend toward urban decentralization and sprawl. Their impacts were largely confined to combating poverty and unemployment, taming the effects of business cycles, mitigating social inequality, and controlling negative externalities (e.g., traffic congestion and environmental destruction).

Keynesian urban policy in the United States traditionally focused largely on the problems of inner cities, including the urban renewal programs of the 1950s, the Model Cities Program of the 1960s, and the Housing and Community Development Act of 1974, the centerpiece of urban policy under the Nixon administration. President Johnson's Great Society programs, including the War on Poverty legislation, were largely concerned with the dire straights faced by the urban underclass, in part responding to the urban riots of the 1960s. In the 1950s and 1960s, under the guise of urban renewal, federal efforts were also aimed at enhancing the commercial viability of downtown areas (e.g., via highway on-ramps and off-ramps), often involving massive displacement of low-income minorities and the obliteration of their neighborhoods. The Urban Mass Transportation Act of 1964 provided federal funds to finance mass transit facilities, which favored low-income areas, and the 1968 Federal Housing Act increased the supply of low-income housing. Under the Carter Administration, the Comprehensive Employment and Training Act in 1978 offered cities fiscal aid, subsidies and public service employment programs and instigated the Urban Development Action Grant program to subsidize the rehabilitation of older industrial and commercial spaces. These programs were augmented by a host of other programs, including Targeted Job Tax Credits and community development block grants.

Neoliberal Urban Policy

Beginning in the United States and the United Kingdom in the 1980s, and subsequently expanding to

encompass many other countries, urban policy underwent a pronounced turnabout with the hegemony of neoliberalism. Typically, this shift was characterized by widespread deregulation and privatization, and by the state's withdrawal from the broad domain of social reproduction (i.e., government financing for public services, especially those aimed at the poor). National governments in many countries altered their funding priorities, eliminated many programs of their predecessors, initiated new ones in keeping with the ideological imperatives of the "free market," and transformed the national policy matrix within which cities are governed.

The transition from national to global markets, and associated internationalization of economic linkages within many countries, made the viability of nationally based state welfarism increasingly questionable. Even in the bastions of state welfarism such as Scandinavia, where social programs have long been regarded as sacrosanct, neoliberalism has induced attempts to reduce social spending. With the neoliberal demise of the welfare state, urban policy in many countries became increasingly less concerned with the provision of social benefits to the poor and needy and more concerned with budget reductions in such expenditures.

In the United States under the Reagan administration, federal subsidies to localities for mass transit, education, water treatment, medical care, and public housing were sharply reduced. This assault on the welfare state had mixed results: While some domestic programs suffered sharp contractions, others, including social security, Medicaid, Medicare, food stamps, and Aid to Families with Dependent Children were sufficiently popular to escape relatively unscathed. Urban Development Action Grants, initiated by the Nixon administration in 1974 and earmarked for specific purposes, were folded into block grants. This shift in funding strategies gave local political authorities considerably more control over the allocation of federal funds during a period in which interurban competition rose sharply. To a considerable extent, block grants subsidized downtown developments without regulating them, contributing to the surge of gentrification in central city areas. Additionally, the "workfare" reforms of the Clinton administration in the 1990s,

which continued under the presidency of George W. Bush, removed tens of millions of people from the “welfare rolls” of public relief, a burden disproportionately felt by cities. Opposition to such measures was frequently labeled as “anti-growth,” and the costs of such projects in terms of residential displacement rarely entered into discourse about their contribution to a broadly inclusive “public good.” Post-Keynesian urban policy thus successively subordinated social needs to the prerequisites of real estate firms, bankers, the construction industry, and related interests.

Neoliberal urban policy also witnessed a sustained devolution of powers from national to local governments. In the United States, this took the form of Reagan’s New Federalism, which shifted financing for many programs to the states. In the U.K., the collapse of Keynesian policy was apparent in the ascendancy of Thatcherism, which centralized many responsibilities formerly controlled by the local state (including the abolition of the Greater London Council in 1985), in contrast to the devolution of governance underway in the United States. However, the U.K.’s City Challenge program spurred competition among the states. Similarly, the Major City Policy in the Netherlands was designed to stimulate local urban economic rejuvenation.

Perhaps the most geographically obvious neoliberal strategy that combined elements of deregulation, privatization, and public-private partnerships was the Enterprise Zone. Originally proposed as a means of unleashing market forces in distressed inner cities through the simple removal of government controls, enterprise zones soon evolved into more complex attempts to generate private investment through active public subsidies (income and capital gains tax breaks, depreciation allowances, labor training programs) in selected urban areas. Enterprise zones, first implemented in the U.K. in 1981, began as an experiment to give inner cities tax relief and freedom from planning restrictions. The British government also created Urban Development Corporations to stimulate property investment, map land uses, and make sites available to developers; in the United States, these assumed the form of Urban Redevelopment Authorities.

A central neoliberal tool in urban policy has been the institution of public-private partnerships.

Advocates of this strategy justify it on the grounds that it illustrates an unproblematic mutual interest between the two sectors: Involvement by the public sector allows for supervision and oversight of projects in which private developers would otherwise enjoy autonomy. Public promotion and facilitation of private development are assumed to produce a general public benefit, that is, positive externalities that include improving a city’s economic base and raising real estate values, thereby generating additional tax revenues that in turn permit greater resources for social redistribution. Moreover, the long-term gains outweigh the ostensibly short-term public subsidies deployed. Corporate interests are attracted to cities that deploy powers of eminent domain, assemble and package land parcels, erect new infrastructures, and offer various subsidies. Private interests are held to contribute expertise, experience, financial resources, and technological and managerial efficiency frequently inaccessible to those in the public domain. The involvement of the public sector in such ventures often allow private interests to claim that they have made contributions to civic welfare. The opportunity costs of government spending on such ventures were rarely acknowledged, including funding that might otherwise have been extended to distressed urban areas.

It should be noted that neoliberal urban policy was not implemented to the same extent everywhere. In Japan, for example, privatization and reductions in social expenditures were considerably less prevalent than in the United States or Western Europe. In France and Southern Europe, too, neoliberal urban policies found much less purchase than in other parts of the continent.

Finally, neoliberal urban policy was influential in the rise of world cities, large metropolitan areas that play powerful roles in the global economy. As national regulations were portrayed as inhibiting competitiveness in a worldwide market, deregulation tended to accelerate the explosive rise of financial and producer services in cities such as London, New York, Los Angeles, Tokyo, Toronto, and, increasingly, Singapore and Shanghai. The health of many such centers has become increasingly more linked to the global economy than to their national ones, rendering them problematic from the point of view of national urban policy makers.

Local Urban Policy Under Neoliberalism

At the local level, the transition to neoliberalism induced a switch from “managerial” to “entrepreneurial” planning, in which local authorities became increasingly preoccupied with attracting capital and generating economic growth at the expense of long-standing priorities such as social equality, protection of the poor and socially marginalized, and environmental protection. In many countries, bereft public authorities became susceptible to the aggressive overtures of private capital, raising the political leverage of investors over local public authorities. Frequently, interurban and inter-regional competition sharply accelerated, forcing public authorities to partake in zero-sum auctions to woo increasingly footloose capital. Typically, older industrial cities suffered while service-based urban areas flourished. Levels of inequality rose accordingly. The broad shift in the priorities of local governments led them to become less concerned with issues of social redistribution, compensation for negative externalities, provision of public services, and environmental management and more absorbed with questions of economic competitiveness, attracting investment capital, and the production of a favorable “business climate.” Long-term capital budgeting, master planning, and infrastructure investments have given way to short-term concerns of job generation, looser regulations, and tax relief. Planning is hence concerned more with promoting economic development and less with regulating its aftermath. In the United States, a common result was widespread commercial sprawl, often in the form of ugly strip malls, in which public land use controls are so relaxed as to be negligible.

In this context, neighborhoods assume importance either through their economic significance or through political power. Frequently, planning resources are allocated toward economically influential areas (e.g., the central business district) or politically powerful neighborhoods (including suburbs and gated communities), but not toward the ghettos populated by the urban underclass that command little attention from urban policy makers. In this way, urban policy reproduces and deepens difficulties endured by the poor, ethnic

minorities, and the politically disenfranchised. Therefore, despite neoliberal rhetoric about how consumer sovereignty depoliticizes urban development, it has in fact politicized planning to an unprecedented degree.

Urban Policy in the Developing World

Societies, governments, and cities in that vast swath of the planet commonly known as the developing world generally face circumstances that differ substantially from those in the economically advanced countries, and hence urban policies differ accordingly. Levels of urbanization range markedly among developing countries, ranging from the minuscule (e.g., much of sub-Saharan Africa) to predominantly urbanized (as in much of Latin America). Rapid demographic growth, rural-to-urban migration, housing shortages, inadequate public services, and widespread poverty tend to be the norm, although the severity and frequency of such problems vary enormously. Moreover, depending on the country, urban policy initiatives may be hampered by lack of adequate funding mechanisms, foreign interference, widespread corruption, shortages of human capital, or inadequate effective leadership. Some developing countries face political divisions, including ethnic conflicts, or widespread distrust of the state based on long histories of oppression, as in post-apartheid South Africa, that hamper effective urban policy implementation. Finally, in countries in which military expenditures have the highest priority, urban policy may fall well behind in terms of planning efforts and implementation.

Many developing countries feature urban hierarchies characterized by primate cities (e.g., Mexico City, Seoul, Buenos Aires, Lagos), in which both public and private investments, and hence employment opportunities, are overconcentrated within a single megacity. (Notably, France also faces this issue.) Urban policies in such a context may attempt to decentralize some government functions to smaller cities (e.g., in Argentina), although such efforts are typically met with stiff resistance.

In many developing countries, housing shortages and problems of accessibility to clean water and air are important obstacles to development.

Because more people rely upon public transportation and public medical and educational services in the developing world than in economically developed ones, much urban policy is concerned with the provision of such services. In countries with rapid growth in population and/or incomes, rising numbers of automobiles can lead to severe traffic congestion, often a centerpiece of urban policy initiatives. Thus, urban sustainability is often a priority in urban policy measures, although its successful achievement via policy initiatives is questionable.

Rapid rural-to-urban migration, and the consequent swelling of urban shantytowns and squatter settlements, present formidable challenges to the provision of public services and control of crime. In such cases, urban and rural policies are inextricably intertwined. Many governments have attempted to meet such challenges by encouraging rural development, including infrastructure development, as a means of reducing the influx to urban areas; others respond with forcible destruction of such communities. Some governments in the developing world enforce price limitations on essential foodstuffs, a policy that critics hold discourages local farmers but reduces the reproduction costs of urban labor, particularly for transnational corporations.

To some extent, Western neoliberal urban policy initiatives have been replicated in the developing world. In China, for example, most urban areas now enjoy greater autonomy in decision making and revenue collection than they did in the past. Structural adjustment programs implemented by the International Monetary Fund may also limit national or municipal authorities' ability to assist low-income populations, as with subsidies for mass transit.

URBAN SOLID WASTE MANAGEMENT

Urban solid waste refers to industrial, commercial, institutional (collectively known as ICI waste), residential, and construction/demolition waste generated in urban areas. Current waste management practices emphasize approaches such as recycling that attempt to divert waste from landfills as much as possible. This is a significant reversal from practices that existed during most of the 20th century, when the main role of the waste management professional was to collect and dispose of waste as efficiently as possible by burning or burying it. Waste diversion has been increasing at a steady pace since the mid 1980s, when governments in most industrialized countries responded to landfill shortages and growing environmental concerns about excessive waste production by introducing municipal recycling programs.

Another significant change in urban waste management since the late 20th century is that it is no longer just a local issue. Because of economies of scale at large waste management facilities, the consolidation of private sector waste management companies, and the lack of local facility capacity, waste disposal and treatment can occur hundreds of miles from the point of generation and even in adjacent countries. Recyclables, particularly waste electrical and electronic equipment (WEEE) and recyclables found in the residues from mechanized material recovery facilities, can be shipped even further for processing. These may end up in lower-income countries, where the labor-intensive separation of different types of recyclables from one another, the removal of contaminants, and the breakdown of recyclable items into their component parts are considerably less expensive but often more environmentally hazardous than in industrialized countries. This entry discusses the waste hierarchy, waste generation, and composition; integrated waste management; the informal sector composed of self-employed individuals who participate in waste collection, separation, and recycling; urban waste management facility siting; and policy tools.

Although recycling is probably the most common waste diversion technique in use today,

nearly all urban waste management policies subscribe to the waste management hierarchy, of which recycling is only one element. The ordering of elements in the hierarchy is seen as problematic by some, but most governments have adopted the following ranking, in order of environmental performance from best to worst: (a) waste prevention activities (also referred to as source reduction or waste minimization) that reduce the mass, volume, or toxicity of a product or material at source; (b) reuse; (c) recycling and biological treatment; (d) thermal treatment (typically with energy recovery); and (e) disposal. Despite the enormous effort being put into diversion of wastes by governments, a disappointing aspect of current urban waste management practice is the lack of attention paid to the root cause of waste production, namely, consumption.

Waste Generation and Composition

Within the broader category of urban waste, waste generated by households, municipal governments, and small commercial and retail generators is known as municipal solid waste. Municipal waste excludes industrial waste—waste generated by large commercial and retail generators and construction and demolition wastes—because these categories are usually managed by the generators rather than by municipalities. Much of the data on waste generation in various countries or cities refer to municipal waste because these data are publicly available and well tracked by municipal governments. However, the data may sometimes include ICI waste, so caution should be taken when comparing data across jurisdictions.

The amount of urban waste generated per capita varies considerably around the world. Because of their wealth, industrialized countries produce considerably more urban waste than lower-income countries, generally on the order of two to three times as much per capita. About one third of the urban waste from higher-income countries is paper, one third is organic, and the remainder consists of plastics, metals, glass, wood, rubber, leather, textiles, and miscellaneous materials. In lower-income countries, a much larger portion of the waste stream is organic, typically from half to three quarters, while paper and plastic waste

constitute 5% to 15%. Lower-income countries have a higher percentage of organic waste because residents consume fewer processed foods (much of the organic waste is produced at the point of processing rather than in the home) and have fewer sources of other types of waste, such as packaging and wastepaper from offices. Inert materials, such as ash residues from cooking fuels, can make up a large portion of the urban waste stream in countries where householders lack access to reliable electricity or natural gas distribution networks and rely on coal briquettes for cooking and heating.

The Waste Hierarchy and Integrated Waste Management

Understanding the composition of urban waste is the first step in managing that waste. A waste stream that is high in organics means that biological treatment, such as composting, should be an essential component of waste management. The energy content of the waste stream is also important in determining waste management approaches. Paper and plastics, for example, have high calorific values, while organics, which are high in moisture, have low calorific values. Burning waste to recover energy is not an effective management technique for lower-income countries, where the waste stream has a large percentage of organics.

One way to assess the environmental impacts of alternative waste management options is through life cycle analysis (LCA). LCA enumerates the energy, water, and material inputs and the outputs of airborne emissions, water effluents, and solid wastes at each stage of a waste material or waste product's life cycle, from the "cradle" to the "grave." The cradle in LCAs of waste management systems is typically the point at which municipal solid waste is set out for collection, and the grave is disposal in a landfill. Recycling, biological treatment, and thermal treatment occur in between. LCA studies confirm that recycling is better for the environment overall than incineration with energy recovery, and that incineration with energy recovery is better than landfilling. These results are generally consistent across all types of materials. In other words, LCA tends to confirm that the waste

management hierarchy is valid in terms of environmental performance, at least in industrialized countries, where most of these studies have been conducted. The one exception is plastics, which a few studies have shown to have higher acidification effects and energy use when they are recycled rather than burned. Another cautionary note in the use of the waste management hierarchy is that it does not consider the social or financial impacts of each option. For example, although incineration with energy recovery may be better for the environment than landfilling, it may also be far more costly and therefore unattractive to municipal governments. An approach known as integrated waste management (IWM) has emerged to address this problem. IWM recognizes the interrelationship of environmental, economic, and social factors in designing waste management systems. It also recognizes that the best system for one location may differ from that in other locations because of geographic variations in, for example, the composition of waste, the availability of markets for recyclables, and the availability of suitable sites for waste management facilities.

The Informal Sector

Almost all countries, regardless of their level of income, have what is called the "informal" waste sector, where waste is collected, separated, recycled, and sometimes reused by self-employed individuals. The sector is unregulated, and individuals do not report their incomes for taxation purposes. Cities in lower-income countries have no formal municipal recycling programs, yet many of these cities divert just as much or more waste from landfills as cities in the industrialized North because of the informal sector. The value of recyclables in the waste stream relative to incomes is much higher in lower-income countries than in the industrialized ones. Householders and other waste generators receive payments at depots or from itinerant buyers, who go from door to door collecting the most valuable recyclable and reusable items. Waste pickers on the street and at open dumps or landfills sort through valuable items remaining in the waste stream. Many people in the informal sector are rural migrants, and most start collecting recyclables because it provides a source of income with few barriers to

entry. Even so, the job is hazardous. Those who pick through waste for recyclables at dumps and on the streets risk exposure to broken glass, pathogens, dust, and other pollutants. It is also a stigmatized profession, whose workers are regularly harassed by police and the public. The informal recycling sector is present in industrialized countries as well. Although much smaller in size, it plays an important role in recycling beverage containers (where deposits exist), scrap metal, and sometimes paper—all collected by picking through garbage and recycling bins or bags. Reuse that occurs at yard sales and car boot (trunk) sales and flea markets are also examples of waste diversion through the informal sector.

In the industrialized world, almost all waste generators receive collection services, but in developing countries, cities often don't have the financial resources to provide collection services, leaving anywhere from 25% to 50% of the city without service. In the absence of municipal collection services, residents burn their waste, bury it, dispose of it in lakes and streams, or leave it in open dumps. Some communities have responded to this problem by creating community-based collection programs, frequently with the assistance of nongovernmental groups. Community organizers gather fees from residents and pay informal workers to collect waste and deliver it to a centralized municipal collection point.

Urban Waste Management Facilities

The infrastructure for managing waste includes a range of facilities, from landfills to incineration or energy-from-waste facilities, to biological treatment facilities (for composting and bio-gasification) and transfer stations (where waste is compacted for long-haul transport). Opposition to the siting of waste management facilities is widespread. Some refer to this opposition as NIMBYism (not in my backyard), a contested term that implies that opposition is about self-interest rather than real concerns. Opponents cite many concerns, including odors, groundwater pollution, air pollution, noise, traffic, dust, and property value impacts. Opposition is present not only in industrialized countries. There are many examples of civil disobedience against the siting and operation of disposal facilities in lower-income countries, where

weak environmental regulations and lax enforcement can produce severe pollution problems.

Policy Tools

A wide array of policy tools is being used to divert waste from landfills. They include regulatory instruments, such as landfill bans on recyclable materials; economic instruments, such as landfill taxes; and voluntary instruments, such as agreements by industry to minimize production wastes. One of the most effective policy tools for encouraging waste diversion in the residential sector is a collection, or user fee. Under a user fee scheme, householders pay for collection of their waste by weight, or more commonly by volume, rather than paying a flat fee or hidden fee in general taxes. Householders can reduce their fees by recycling more, by using home composters, and by purchasing products with less packaging or more durability.

Another increasingly popular policy tool for waste management in industrialized countries is extended producer responsibility (EPR). EPR places partial or full responsibility for the postconsumer stage of a product's life cycle on the producer of that product. A basic principle of EPR is to shift the burden of paying for waste management costs from municipalities and the general taxpayer to the producers and consumers of particular products. Europe has been a leader in EPR, starting with Germany's 1991 packaging ordinance, in which producers were required to take back and either recycle or recover energy from specified percentages of postconsumer packaging. In 1994, the European Union's Packaging and Packaging Waste Directive introduced targets for the recovery, recycling, and heavy metal content of packaging waste and stimulated a wave of EPR packaging policies among its member countries. WEEE, waste batteries, and end-of-life vehicles are also subject to EPR policy in the European Union. By placing responsibility for postconsumer products and materials on the producer, EPR is meant to encourage producers to make design changes to their products that will reduce waste management costs. Such changes could include making a product easier to recycle or reuse, reducing packaging, and a variety of similar changes collectively known as design for environment (DfE). Although EPR

has been successful in transferring waste management costs to producers, it has not been as successful in encouraging DfE. There are many reasons for this lack of success, prime among them being that many EPR policies allow producers to meet diversion targets collectively, for the industry as a whole, rather than ensuring that individual producers meet waste diversion targets for their own products. Future generations of EPR policy may be more effective in achieving the DfE goal and at reducing waste at source.

URBAN SPATIAL STRUCTURE

In economically advanced, postindustrial countries such as the United States, the proportion of people living in towns, cities, and metropolitan areas reached 75% or more by the late 20th century in developed countries. In the world as a whole, the proportion of urban population rose from less than 5% in 1800 to slightly more than 50% of a much larger aggregate world population by the early 21st century. Numerically, world urban residents expanded from perhaps 30 million

in 1800 to about 3 billion in 2000. Matters of urban spatial structure, which pertain to the geographical patterns and characteristics of urban places, thus concern a very large and expanding share of the world's people. This entry examines the factors that influence urban spatial structure and how they contributed to growth in urbanization in the United States. It then discusses the ways in which geographers have conceptualized urban spatial structure through the concentric zone, sector, and multiple-nuclei models and also considers the limitations of these models. The entry concludes with a look at how urban spatial structure may evolve in the future.

One major facet of urban spatial structure involves the overall geographical patterns of urban settlements at regional, national, and global scales, especially in terms of the sizes and locations of towns, cities, and metropolitan areas. Another major facet involves the internal spatial arrangements of activities and land uses within urban settlements. Indeed, one of the most common analytical distinctions made in urban geography reflects a division according to geographical scale into matters that involve, first, “interurban” features of “systems of cities” for cartographically smaller map scales, at which towns, cities, or metropolitan areas are most reasonably represented using point symbols, and, second, “intra-urban” characteristics of city systems for cartographically larger map scales, at which the internal features of towns, cities, or metropolitan areas are most reasonably represented using line or area symbols. In between these are intermediate geographical scales, at which urban land use and activity patterns can be examined for metropolitan regions, which are conventionally subdivided into central city, suburban, and fringe subareas.

Patterns of Interurban Spatial Structure

Economic and environmental considerations usually predominate when one tries to understand the spatial structure of an overall interurban system of cities.

Economic Functions

While differences in the social, cultural, political, or demographic characteristics of cities create

Figure 1 Population sizes of Eastern U.S. cities, 2000. The intra-urban morphology of cities is closely bound up with the evolving interurban system of cities.

Source: Author.

an enormous diversity of urban lifestyles, it is the differences in their economic functions that largely account for geographical variations in their rates of economic growth and levels of economic well-being. Some cities are mainly mining centers, known for their mineral, petroleum, or natural gas industries. Others are mainly manufacturing centers, known for the production of nondurable goods, such as chemicals, textiles, or food products, or durable goods, such as electronic or transportation equipment. Most cities perform trade or service functions, which include the collection and wholesaling of agricultural products,

warehousing, retail trade, and the provision of diverse educational, medical, governmental, and other services. Industrial location theory, central place theory, and regional growth theory all help improve understanding of how cities with different economic bases function within a larger system of cities. Cities mainly specialized in goods production or handling have generally grown more slowly than cities mainly specialized in services, especially consumer or producer services. Indeed, at the very top of the world urban system are “global” or “world” cities, such as New York, London, and Tokyo, which owe their elevated status and success to the provision of a wide range of financial and producer services. Major transnational corporations generally have their headquarters located in world cities, even though their production facilities are often dispersed among many smaller urban and rural settlements.

Environmental Settings

Even in the modern postindustrial era, the environmental settings of cities remain important. For example, many of the largest cities in the Eastern United States are located along or near a seacoast or lake front, including New York, Chicago, Philadelphia, Washington, and Miami (Figure 1). Other major cities can be found along interior waterways, such as Minneapolis, St. Louis, New Orleans, and Pittsburgh, which originated and continue to function as Mississippi or Ohio River ports. The surrounding fertile agricultural lands, as in the Corn Belt or Great Plains; the nearby deposits of minerals or fossil fuels, including iron ore, coal, oil, or natural gas; or adjacent forest or mountain amenities are of importance to cities

such as Kansas City, Dallas–Fort Worth, Birmingham, or Houston. Changes in technology and in consumer tastes create continual reassessments of natural resources, causing some cities to experience booms while others lag behind. More leisure time has made amenity-rich locations especially attractive in recent years.

Patterns of Intra-Urban Spatial Structure

While economics and environment usually feature prominently in geographical discussions of systems of cities, much more varied terminologies can be encountered in geographical discourses focused at the intra-urban city system scale of daily urban experience. At this scale, an urban or metropolitan settlement represents the geographical context in which most people live and work. Refined land use specialization usually is regarded as one of the defining characteristics of urban existence in a postindustrial society, such as that of the United States. Nearly two thirds of Americans now live in owner-occupied, single-family detached homes, which increasingly are located in suburban settings. Most other Americans live at higher residential densities in duplexes, apartments, or high-rise condominiums, which mainly are located in inner-city settings. Less than 7% of Americans lived outside the “core-based” Metropolitan or Micropolitan Statistical Areas in 2006, and less than 5% lived on farms or ranches in rural settings.

The Emergence of Urbanization in the United States

In any thoughtful consideration of the spatial structure of urban settlement, it is worth keeping in mind that barely two centuries ago, at the time of the first U.S. Census in 1790, about 95% of Americans lived on farms, and the largest city, New York, had a resident population of only about 49,000 people. In comparison, in 2006, there were 363 urban settlements in the United States, which exceeded the 50,000 population threshold for Metropolitan Statistical Area status, and the New York Consolidated Metropolitan Statistical Area alone contained an estimated population of more than 18.8 million people. These enormous changes in urban

demography have been paralleled by equally impressive changes in urban transportation, communications, and construction technologies, which make it possible to move people, goods, and ideas much faster and higher in the modern, machine-powered city than was possible in the earlier, muscle-powered city. The 19th-century city was transformed by electric trams, commuter railroads, landline telephones, and electrically powered elevators just as much as the 20th-century city was transformed by private automobiles, television, wireless cell phones, and high-speed Internet connections. In New York City, in 1790, virtually everyone had to walk to school, workplace, or shop; in New York City, in 2006, there were so many transport choices among so many modes of surface or subway and steel-wheeled or rubber-tired conveyances that some residents regarded walking as a recreational exercise.

Most modern urban geography texts devote at least two thirds of their contents to matters that involve intra-urban spatial structure. When urban geography first supplanted rural settlement geography as a realm of excitedly expanding geographical discourse about the middle of the 20th century, the split between interurban and intra-urban topics was usually about even. But intra-urban topics now predominate to such an extent that their page coverage in a typical urban geography textbook echoes the proportion of the U.S. population that lives in metropolitan areas with populations of 1 million or more, a proportion that noncoincidentally is about 60%. When Metropolitan Statistical Areas of all population sizes are considered, it is found that their areal extent spans about 20% of the total U.S. land area, although Urbanized Areas, which comprise the more densely populated built-up portions of urban clusters, cover only about 5% of all U.S. land.

Models of Intra-Urban Spatial Structure

The question of whether broad geographical generalizations can legitimately be drawn about the myriad, complex, and subtle urban spatial structures to be found within these urban settings is generating tension between urban geographers who tend to view the city from a positivist,

model-building perspective and those who tend to view the city from a softer and more nuanced, postmodern perspective. These poles can be represented, on the one hand, by computer-based quantitative factorial ecologies that mathematically summarize vast arrays of hard areal statistics and, on the other hand, by eloquent and sometimes adamant descriptions of “street-level participant observations” made in inner-city settings. In between these two perspectives, there are perhaps some commonalities of view among interested urban geographers regarding at least some of the basic features of intra-urban spatial structure.

Virtually every recent urban geography textbook includes a section dealing with the “three classic models” of urban spatial structure (Figure 2). In a way, these three classic intra-urban models are rather like the three “essential” filters that an aspiring photographer should have handy to photograph through atmospheric haze (haze filter), to avoid reflections (polarizing filter), or to focus on small subjects (close-up filter). These simplified abstractions scarcely guarantee a “perfect picture” of the city, but they can direct attention to revealing and worthwhile vistas.

Concentric Zone Model

The concentric zone model can be thought of as presenting a view that enables a city or metropolitan area to be visualized as if from a high altitude. Google Earth is a handy Web-based source for high-altitude views of most cities in the United States, as well as elsewhere. Details merge into very broad patterns if a city is viewed from high above, but a dominant geographical core central business district (CBD) usually can be identified by finding the tallest buildings and by observing the convergence of major transportation lines. Dense workday populations, traffic congestion, and high land values also usually characterize the CBD. According to urban “bid rent” theory, commercial or institutional activities are more likely to be able to profit from and hence pay for scarce and expensive sites near a city’s Peak Land Value Intersection. Commercial and institutional activities therefore tend to dominate within the CBD. Outward from the CBD, competition for space among activities with differing capacities to profit

from accessibility leads to an overall pattern of concentric zones. As distance from the CBD increases, this pattern can be physically manifested by lower building height and perhaps larger lot size, demographically manifested by lower population density and perhaps by different population characteristics in terms of age structure or ethnic composition, and economically manifested by lower land value. With notable exceptions such as New York’s Central Park or Boston’s Common, there usually is very limited green space in most CBDs, but open land becomes more common and finally predominates as the urban periphery is reached.

According to the concentric zone model, most famously articulated by the urban ecologist Ernest W. Burgess for Chicago in the mid 1920s, the CBD is usually surrounded by a zone in transition, within which anticipated land use change discourages maintenance, leading to physically decaying structures occupied by wholesaling or light manufacturing activities unable to afford the high rents of the CBD, followed in succession by “lower-status,” “medium-status,” and finally “higher-status” residential zones. In Burgess’s era, only members of the wealthy elite could afford large peripheral estates and indulge in fashionable midmorning work trips on a comfortable commuter railway line. Economic necessity forced everyone else to live closer to their place of work and to travel by crowded public buses, trolleys, and subway or elevated trains.

Sector Model

The sector model can be thought of as presenting a view that allows pronounced directional biases to be detected in urban spatial patterns. The dominance of the CBD remains apparent, but distance decay effects are no longer so uniform as to create perfectly symmetrical zones in any direction outward from the CBD. Instead, transport corridors, water fronts, historical attachments, and other directionally biased influences lead to radial variations in land values, land uses, and neighborhood characteristics in different directions outward from the CBD. Homer Hoyt’s Depression era research on residential patterns in many American cities showed that appealingly comfortable and highly valued residential properties

Figure 2 Models of urban spatial structure. The Chicago School models greatly influenced the subsequent trajectory of thought about the structure of cities.

often dominate along high-status corridors from near city centers outward, as northward from the Loop along Lakeshore Drive in Chicago or north-westward from Capitol Hill toward Georgetown and beyond to Chevy Chase and Bethesda in the

Washington, D.C., metropolitan area. Although Hoyt's generalizations were asserted during the heyday of the streetcar, many continued to be applicable during the late-20th-century freeway automobile era, though at a much expanded

geographical scale. In the greater Washington, D.C., metropolitan area, for example, the fashionable Northwestern Corridor now extends much further outward along Interstate 270, beyond Rockville toward Frederick, Maryland.

Multiple-Nuclei Model

The multiple-nuclei model can be thought of as presenting a view that reveals distinctive and usually rather homogeneous districts of many varieties. On the commercial side, financial districts group banks, stock brokerage firms, and related services near one another; entertainment districts are formed by geographical clusters of theaters, restaurants, and perhaps sports arenas; automobile districts cluster new and used car dealerships and automobile repair shops; warehouse and light manufacturing districts feature clusters of often functionally linked production facilities; airport districts cluster around airfields; port districts line waterfronts; and so on. On the residential side, there are high-rent clusters of luxury townhouses and high-rise condominiums; “zones of dependence,” with geographical concentrations of decaying multifamily private and perhaps public housing units; and so on. On the institutional side, college or university districts cluster academic classroom and research facilities near student housing and college-oriented businesses such as bookstores and bars; medical districts group nearby general and specialty hospitals and physicians’ offices; and so on. As a rule, districts tend to be larger, more highly specialized, and more distinctive in larger metropolitan areas and less distinctive in smaller cities and towns, though a tendency to geographically cluster similar or functionally linked land uses exists throughout the urban hierarchy, as evidenced, for example, by the clusters of feed, fertilizer, and farm equipment suppliers in small rural service communities in the Midwest.

Diversity, Spatial Specialization, and Urban Futures

Three final points about urban spatial structure remain.

First, towns, cities, and metropolitan areas are extraordinarily diverse in their geographical

patterns, especially when considered at local or neighborhood scales. In any urban settlement, if one were to walk down a street, ride a bus, or look out from an upper-story window, he or she is likely to see a colorful variety of people, land uses, and activities. The three simple classic models described here, and even their more complex and sophisticated counterparts, are abstractions that may generalize but cannot entirely capture the on-the-ground character of a real city.

Second, spatial specialization at an urban or metropolitan scale can have Janus-like implications. Janus, the Roman god of doors, gates, and beginnings, is represented artistically with two opposite faces. On the one side, spatial segregation of people and activities can increase well-being by giving urban residents utility-maximizing choices of geographical settings that most appeal to them, in terms of architectures, public services, shops, neighbors, lifestyles, and so on. But on the other side, service needs and the fiscal capacities to meet these needs can become severely geographically mismatched. This problem is especially conspicuous in larger and older metropolitan settings, where the richer suburban municipalities are politically, administratively, and legally quite separate from the seriously underbounded central cities. In such settings, gated communities quite literally wall service demands out and fiscal resources in.

Third, urban spatial structure is very dynamic through time. The degree of dynamism is especially conspicuous in North America, where small towns grew into giant metropolises in a historical blink of an eye. But in the early-21st-century period of steeply rising energy costs, the future of urban spatial structure seems uncertain. The second half of the 20th century witnessed rural-to-urban land conversion at a prodigious rate, as expanding freeway systems pushed further and further outward from city centers. But expensive gasoline is likely to diminish the appeal of distant suburban commuter zones, affecting building trends and home values throughout the metropolitan regions. Big sedans and SUVs (sport-utility vehicles) with gas-guzzling engines are beginning to filter down through the used car market to congest the parking lots of inner-city public housing projects. Pedestrian-friendly New Urbanism developments are likely to become increasingly fashionable. Privately planned New

Urbanism communities feature mixed land uses, narrow residential lots, and small-town-like neighborhoods with schools, churches, shops, or offices within easy walking distance of homes. Imagine a gaslight-illuminated Victorian-era streetcar suburb but with a small, fuel-stingy hybrid gas-electric car parked in front of each bungalow, and one just might be looking back into the North American urban future.

URBAN SPRAWL

The term *urban sprawl* should be understood in the context of a deep-seated and ongoing conflict over differing visions of and priorities for the development of urban regions, between those who see contemporary suburban land development patterns as a good thing and those who see them as a major social and environmental problem. The meaning and image of urban sprawl are contested and are thus continually evolving, but most discussions of urban sprawl identify a number of common characteristics, including low-density residential development on the urban fringe, segregated land uses that give rise to long-distance travel and dependence on automobiles for mobility, and leapfrogging of development over undeveloped areas.

Although critiques of urban sprawl have become increasingly prominent during the past three decades, concern about patterns of urban expansion was a major issue for planning advocates in Western Europe and North America in the early 20th century. Their argument was that planned suburban growth offered a chance to prevent the problems of overcrowding, disease, pollution, and congestion that plagued 19th-century industrial cities and that unplanned urbanization would merely produce more of the same. A major goal of the early planners was therefore to be able to regulate and plan for development on the fringe, to ensure that housing areas were separated from industry; road patterns were well designed; water, sewer, and public transit facilities were built; and parks and natural areas set aside. Although most developed countries had enacted some elements of city planning legislation before World War II, powers were limited, and most development continued to be unplanned.

After the war, increased city-planning powers, rapid economic growth, and a spurt in house building led to the development of expansive new suburban areas with single-family, detached homes. Zoning regulations designed to avoid the problem of mixed housing and industrial areas encouraged the creation of purely residential developments, while the mobility offered by widespread automobile use meant that land was cheap

Aerial view of San Jose, California. The intersection of Interstate 280 and California State Route 87 (Guadalupe Parkway) is visible at the bottom of the photograph.

Source: Robert Campbell/U.S. Army Corps of Engineers Digital Visual Library.

and housing could be built for all classes at relatively low densities. Early in this postwar residential boom, the term *urban sprawl* was coined to describe the new patterns of suburban residential development. Early critiques were in part aesthetic, as observers reacted with shock to the enormous scale of the transformation of rural landscapes into homogeneous tracts of single-family homes that were widely seen as ugly.

Over time, however, as the scale of suburbanization accelerated, with ever-larger and more dispersed patterns of development during the past 50 years, the critiques of urban sprawl became more sophisticated and were supported by a growing range of actors. These include many municipal governments and planners, who must deal with the high infrastructure costs of low-density and leapfrog development patterns that leave tracts of land undeveloped; environmentalists, who show

that sprawl consumes far more land than necessary and threatens wildlife because scattered development leads to habitat fragmentation; transport planners, who see low-density, segregated land uses as the major cause of traffic congestion even with high levels of investment in roads, because virtually every trip must be made by car; health advocates, who argue that automobile-dependent suburbs contribute to ill health and obesity by making walking and bicycling difficult; those concerned with social equity, who see the high levels of racial and economic segregation of American society as in large part a product of the white flight to affluent suburbs, which left the poor and racialized minorities to reside in the crumbling inner cities; and those concerned with global warming and environmental sustainability, who see automobile-dependent suburbs as unnecessarily wasteful of fossil fuels.

Sprawl hits the wall (but then goes around it): the Golden State and Antelope Valley freeways in the San Gabriel Mountains in the northern part of Los Angeles County

Source: Michael Dear. Used with permission.

Although some observers dismiss critics of sprawl as elites who merely wish to impose their own aesthetic preferences on the rest of the population, there do appear to be substantive reasons to question the long-term viability of contemporary patterns of extensive suburban growth. And although all developed countries have struggled with the implications of the mobility offered by widespread car ownership, similar conflicts over suburban development played out quite differently in different countries. For example, many Northern European nations have created relatively powerful public controls over suburban development and design, while among the developed countries, the United States and Japan have taken the opposite approach with much weaker regulation and greater freedom for private property developers.

Critiques of sprawl have led to the elaboration of at least three main programs for a different

pattern of urban development: (1) new urbanism, (2) smart growth, and (3) sustainable cities, each of which are premised on the idea that sprawl is a major urban problem and that alternative and more compact urban forms should be a major policy priority. It has not proven easy, however, to stop the growth of sprawl, because existing development patterns have a great deal of momentum and are strongly supported by those with vested interests in continued development, such as urban fringe landowners, developers, construction and building material interests, realtors, and the myriad other actors who profit directly from land development and have powerful incentives to resist new regulatory controls and infrastructure obligations. Also resistant of greater regulation, however, are others, including some affordable housing advocates, who fear that increased regulation will drive up housing prices,

and advocates of free markets, who see any state intervention as an infringement on private property rights. Another major obstacle to attempts to limit urban sprawl is the fragmentation of local government in most metropolitan regions, which makes coordination difficult and can promote competition between jurisdictions for desirable development and the exclusion of unwanted land uses, each of which can contribute to further sprawl. It seems highly likely that urban sprawl will continue to provoke controversy.

URBAN STORM WATER MANAGEMENT

Urban storm water management is concerned with the draining of urban areas during and following precipitation as well as dry weather flows. Historically, urban storm water management has focused on managing flood risk through the transit of precipitation within drainage systems, with either combined (sewage and surface water, e.g., the United Kingdom) or separate (surface waters

only, e.g., Australia) systems. The aim of separate systems has been to channel the water rapidly, and often invisibly, to the nearest watercourse, while combined systems use the runoff to flush the system, reducing the likelihood of blockages but often requiring water treatment prior to release. Early examples of urban storm water management exist from the Minoan (e.g., Crete) and Greek (e.g., Pirene, Turkey; see first photo) civilizations. One of the longest-maintained systems is the Cloaca maxima in Ancient Rome, which provides an early example of urban storm water management, with drains collecting rainfall, draining marshlands, and transporting effluent to the river Tiber. London and Paris developed extensive sewer systems in the mid 19th century to remove the bad odors, believed at that time to be the cause of cholera. These systems were indeed responsible for significantly reducing the incidence of cholera, although this was because they led to a significant reduction in the contamination of local drinking waters. The expansion of urban areas during the past century has seen many new challenges within urban water management. As the proportion of catchments covered with impervious surfaces has increased, the quantity and quality of the runoff have changed. These challenges have been particularly acute in the rapidly urbanizing parts of the developing world.

Surface water flows are relatively unpredictable and exceedingly difficult to control, as the source—precipitation—is inherently stochastic. The amount of water discharged into drains varies depending on the duration and intensity of precipitation and the extent to which it can infiltrate into pervious surfaces.

Sewers fail when the infrastructure fails, such as when a blockage occurs or when the sheer volume of precipitation entering them exceeds their design capacity. The design of a piped infrastructure capable of providing drainage for all precipitation magnitudes is unfeasible on economic grounds; as a result, there is always the risk of system failure due to incapacity. Flooding risk is normally expressed as a statistical measure (probability ratio), based on a return frequency, such as a 1-in-100-year storm event.

Varying precipitation levels mean that combined sewers have to convey varying quantities of wastewater at varying concentrations. When

these systems are overloaded during heavy precipitation events, in an attempt to reduce the pressure on the system, untreated waste may be discharged into the nearest watercourse via a combined sewer overflow (CSO), with an obviously negative impact on the environment. On rare occasions when CSOs do not function properly, wastewater can circumvent the constraints of the system, potentially flooding streets, homes, and businesses.

Developers and water system managers are increasingly under pressure from environmental agencies and local authorities to implement approaches to mitigate the risk of flooding. The management of urban drainage in a sustainable manner has increased in importance in recent years. In North America, these approaches are often considered as *best management practices* (BMPs); in Europe, they are known as *sustainable drainage systems* (SuDS); and in Australasia, they are called *water-sensitive urban design* (WSUD). The aim of these systems is to reduce the impact of storm water runoff on receiving rivers, as storm water runoff adversely affects the flow regimes, causing river hydrographs to peak sooner, often at higher levels; the runoff may also wash contaminants into the watercourses, such as organic litter, soil/dust, salt, metals, fertilizers, pesticides, chemicals, oils, hydrocarbons, and a range of other substances that may accumulate on surfaces. The approaches applied depend on the specific issues presented at each site: the duration and intensity of precipitation events; the proportional area covered by impervious surfaces; catchment relief; the drainage system, both natural and anthropogenic, and the level of integration between the two; and land use, with urban areas often including residential, retail, and industrial developments and car parks.

Drains run along the surface of a street in Pirene, Turkey, but a drain also runs beneath the road surface.

Source: Author.

Current water management approaches focus on the sources of runoff and pollution and the tools used to contain and reuse the water within parkland, urban housing, and commercial and industrial areas, with the ecological status of the area and the receiving water bodies of particular importance. The water management approaches used increasingly attempt to reproduce the natural processes of infiltration, which do not operate when using impervious surfaces. Examples of this include the wider use of “green roofs” (see Prague photo), which retain the precipitation within planted beds, or replacing impervious surfaces with systems such as porous paving, which

Green roof on a superstore in Prague, Czech Republic

Source: Author.

permits the water to drain through. These approaches, although successful in many areas, are costly and difficult to retrofit, particularly within urban areas, though increasingly these are being seen as key at the planning stage in gaining planning permission, particularly for large developments. Storm water is increasingly treated as a resource that can bring environmental, economic, and social benefits to urban areas; with capture, treatment, and reuse, storm water can provide an important contribution to water use within urban communities.

Urban storm water management in developing countries is of particular importance with these areas currently facing the greatest challenges to public health resulting from the meager provision of potable (drinking) water, inadequate drainage, and rapid urban expansion. The greatest challenge within developing countries is balancing the demands to provide sanitation and water supply with financial constraints and environmental management. In developing countries, specific challenges exist, with relatively few resources

given to infrastructure development and often relatively poor planning of new developments. Rapid growth often takes the form of informal settlements, with little management of basic infrastructure, as a consequence of which developments are often constructed in unsuitable areas, such as the floodplain or on high gradient slopes. Often, the administrative requirements for successful storm water management are not present, with limited coordination between bodies and across administrative boundaries, leading to poorly integrated drainage systems. The challenges faced by developing urban centers are not new, but the opportunities are also challenges, particularly from a financial and resources perspective.

Historically, drainage has been perceived to be the domain of the civil engineer, but the successful implementation of modern-day urban storm water management requires an integrated approach involving an interdisciplinary team of groups and individuals, including engineers, hydrologists, urban planners, environmental scientists, economists, social scientists, and

developers, who engage with communities and local bodies.

URBAN SUSTAINABILITY

As a concept and a field of study, urban sustainability emerged out of the sustainable development movement that took off in 1987 with the publication of the Brundtland report, *Our Common Future*. Via the Brundtland report and the subsequent 1992 United Nations Conference on Environment and Development (Earth Summit), held in Rio de Janeiro, sustainable development brought together the international priorities of poverty alleviation and environmental conservation, creating an agenda for simultaneous improvement in both situations worldwide. Sustainable development has since been defined in terms of the quest for a balance between economic, social, and environmental conditions and, in the form of “sustainability,” as the achievement of a state of living that can be continued long into the future without deterioration of any of these three. The field of urban sustainability can be viewed from the perspective of international development and prescriptions for global

and intergenerational equity and from the perspective of specific urban development and design tools and techniques, realizing the efficiencies of urbanization and building on case studies. Urban sustainability has a different significance for urban developers, city managers, social justice advocates, and urban dwellers. This entry discusses the diverse agendas and practices of urban sustainability, as well as research perspectives on the topic.

The Urban Sustainability Agenda

The emergence of urban sustainability as an important concept in international development corresponds with the tipping of the balance of the world's population toward a majority of urban, rather than rural, dwellers. This balance was tipped sometime in the first decade of the 21st century, depending on which population estimate is used. Correspondingly, UN-HABITAT, the United Nations agency responsible for local settlements, has taken on urban sustainability as a key challenge. Thinking about urban sustainability in the context of the less developed world brings the human dimensions of sustainable development into focus—that is, the part of the original Brundtland definition that emphasizes poverty alleviation and meeting the needs of the current generation. In the developed world, where the means exist to provide for these needs, the other component of the definition, its focus on intergenerational and environmental equity, is more aptly tackled. Coordinated action by developed and developing nations alike would, of course, be ideal. Some point to significant opportunities for “leapfrog” development, by which the developing world might draw on the experience and expertise of the developed world to bypass the most unsustainable stages of development and create green, sustainable cities before many developed world cities are able to make this transition. This ideal is complicated in practice by the higher up-front costs of green development, the fact that many new technologies are unproven, and the sentiment throughout the developing world that those primarily responsible for the unsustainable state of our cities should be the ones to incur the costs of the sustainability transition.

A common framework for urban development is needed that incorporates the impacts of decisions well into the future as well as around the world. However, initiatives in governing cities with an eye further into the past and the future—such as Portland’s attempts to meet the Kyoto Protocol carbon emissions reduction target or the goal of Masdar City, Abu Dhabi, to generate zero carbon and zero waste by 2016—paradoxically can decrease accountability and action. The politicians and professionals of today will rarely be affected personally by the failure of their projects and goals beyond the horizon of the immediate future, and comparisons with past conditions can be manipulated in any number of ways. The public attention that flows to cities that make grand plans and targets is rarely, if ever, sustained long enough to track their progress, as the standard metrics for evaluating concepts such as carbon neutrality and zero waste do not exist and public and political preferences and pressures are certain to change significantly over time.

Initial studies in urban sustainability were concerned with the impact of cities on sustainable development globally. Coming from an ecological perspective, many sustainability advocates were ambivalent toward or openly derided cities, with scholars such as William Rees going so far as to label cities as ecological black holes. This characterization is justified by the fact that cities develop via the destruction of their local ecologies and their replacement with paved surfaces, biologically unproductive land uses, and the consumption of natural resources far beyond their actual footprint on the landscape (what Mathis Wackernagel and William Rees call the ecological footprint). To most ecologists, cities represent artificial landscapes, in contrast to those composed of mostly nonhuman elements. Furthermore, cities are centers of finance and politics, where many of the most environmentally destructive decisions are made; centers of education, where people are taught the lessons and skills that lead to widespread discounting of natural wealth and productivity; and centers of culture, where these decisions, lessons, and skills are normalized and reproduced. According to this thinking, the surest path to sustainability would be large-scale deurbanization and a return to small, “human-scale” settlements; reliance on “appropriate”

rather than high technology; and primarily local rather than global trade patterns. There are some cases in which this theory can be considered to hold: A number of Rust Belt cities in North America, for instance, are more sustainable settlements following their decline than when they were prosperous, and experimental sustainable communities such as Findhorn, Scotland, and Arcosanti, Arizona, have been established quite consciously apart from the city. Still, the implications of this strain of thinking about sustainability, when applied globally, are troubling in that cities are home to an increasing majority of the world’s people and high rates of urbanization are associated with greater levels of freedom and human rights around the world.

The embodiment of sustainability in the urban realm was raised as an issue by scholars who noticed what Andrew Light called the “urban blindspot” in sustainability and related fields. They noted that, despite the currently destructive state of urbanism, the potential for cities to be beacons of sustainability is great. Efficiencies exist in nearly every realm of urban development: energy efficiencies through shared walls in apartment buildings compared with single-family homes; economic efficiencies through multisectoral industrial clustering, as in the case of eco-industrial networking; and efficiencies in social marketing and rapid changes to social norms toward more sustainable values through, for example, large-scale public demonstrations for climate action; international gatherings such as Earth Summits; and personal lifestyle change efforts such as Earth Day pledges and reusable shopping bag campaigns. Here, the primary notion is to work with the urban advantage that stems from high population density in contrast to the unsustainable resource use and lifestyle patterns found in the suburbs. Positive action in this realm has been pursued primarily by those who study and practice urban design. The designer’s sustainability toolbox consists of ideas such as smart growth, cradle-to-cradle design, zero waste, carbon neutrality, one-planet living, new urbanism, green building, transit-oriented development, and life cycle analysis. Working examples of sustainable design exist as neighborhoods within cities, such as Freiberg, Germany, and Fremantle, Australia.

On July 22, 2009, the U.S. Postal Service dedicated its first “green” roof, the largest in New York City and one of the largest in the country. This photo shows detail and a cross section of the roof, which is on the Morgan mail facility in midtown Manhattan. Built in 1933, the 2.2-million-ft.² facility became a historic landmark in 1986. Its roof was constructed originally to serve as an additional mail processing location, supporting 200 lb./ft.² When the roof was scheduled for replacement in 2007, it was deemed strong enough to support the weight of the soil, vegetation, and other requirements of a green roof. The roof will last up to 50 years, twice as long as the roof it replaced. It will also reduce the amount of contaminants in storm water runoff flowing into New York’s municipal water system. The agency projects the reduction of polluted runoff to be as much as 75 % in summer and up to 35 % during winter.

Urban Sustainability in Practice

In professional practice, urban sustainability presents new challenges for the processes of developing, redeveloping, and managing cities. In theory and to some leading-edge cities, urban sustainability represents a new holistic management framework more than any particular process or policy. In this way, urban sustainability is being applied within a small but growing number of city halls to issues of immigration and integration, poverty alleviation and slum upgrading, improving environmental management and environmental impacts, urban design, regional planning and combating

sprawl, downtown revitalization, housing, transportation, and risk management—the full gamut. Often, these considerations are grouped in terms of the “brown agenda” of urban sanitation and infrastructure; the “green agenda” of environmental services and resource and energy conservation; and the social agenda of developing just and fair institutions and opportunities in the arenas of economics, education, health, governance and so on. As the social agenda remains the least well understood and least well addressed of the urban sustainability domains and given that its scope is so broad, this domain is often broken down into subgroups such as culture, governance, and education.

Research Perspectives on Urban Sustainability

In the early 21st century, while increasing numbers of cities are establishing sustainability branches and functions, the majority of cities with sustainability policies do not clearly differentiate these from environmental policies, offices, and functions. What specifically makes an urban policy oriented toward sustainability as well as what makes a sustainability policy specifically urban are both questions under examination and experimentation. In line with the sustainable development mantra to “think globally, act locally,” different local conditions make different policy approaches suitable. Developing world cities may adopt a sustainability approach to find better, long-term solutions to the state of slums and life conditions of slum dwellers, while a developed world city in decline might pursue a shift to a new economic base, and a thriving developed world city might leverage a building boom or mega event toward sustainability principles.

From an ethical perspective, inquiry into urban sustainability needs to ask, “What is it we are interested in sustaining?” The answer depends on one’s perspective. For city managers, planners, and elected officials, their particular cities need to be sustained over the long term, and a comprehensive approach to maintaining or enhancing its economic, social, and environmental conditions is the preferred strategy. In this context, we need to ask whether a sustainability agenda can be reconciled with pressures for global economic competitiveness, in which most if not all cities are engaged. It is also important to investigate where the responsibility for achieving urban sustainability lies and the opportunities and limitations for action at the scale of particular cities, by urban governments and their citizens, compared with those of higher orders of government, international bodies, and global civil society.

For social justice advocates, it is the lives of urban dwellers worldwide that need to be made sustainable. With an estimated 30% of the world’s poor living in cities, Sudhir Anand and Amartya Sen ask how sustainable development can be a meaningful concept when the living conditions of so many are too deplorable to be worth sustaining. In this context, urban sustainability demands

a narrowing of social and economic disparities, which are often exaggerated in cities. This means correcting long-standing imbalances and relieving poverty and other inequities through social policies and redistributive economic programs that are informed by a holistic approach. The alignment of urban sustainability and democratic agendas becomes apparent here, bringing into focus research questions relating to the relative role of the public and of experts, of social capital and urban citizenship, and of various forms of public participation in urban sustainability.

For urbanists, it is the city, as the dominant kind of human settlement, and the global urban system that need to be brought into balance with the nonurban world. On this point, some researchers point to the value of increasing the resilience of cities for a future sure to be filled with intense shocks and threats, from climate change and economic and social upheavals. Others, such as David Satterthwaite, are primarily concerned with the role that moving cities toward sustainability can play in achieving sustainable development at the global scale. This would mean planning for resilient cities, not just in terms of their own long-term needs and contributions but also in terms of building and maintaining equitable long-term relationships with all other cities in the global network, and thinking about flows of immigration, trade, tourism, ideas, and environmental goods and services around the world. Satterthwaite poses this distinction between inward- and outward-looking sustainable cities in terms of the following question: Sustainable cities or cities that contribute to sustainable development? It is at best disingenuous to talk about sustainability at a local scale if it is achieved by transferring costs, inequities, or waste products elsewhere; at worst, it is the active perpetuation of environmental injustice. The pursuit and study of urban sustainability entail a perspective that moves from the local scale of a single city, down to the individual neighborhoods, businesses, parks, and natural areas within it, and up to the global scale of the world system of cities. The quest is for more effective integration of the diversity of needs and interests operating within and among cities. It is a challenge to consider the impacts and implications of actions for the very long term, respecting the vast diversity of

conditions and aspirations for the future that may emerge.

URBAN UNDERCLASS

The term *urban underclass* has been extremely controversial in the social sciences since its ascendancy in the early 1980s. The term, coined by Gunner Myrdal in 1962 to describe a stratum of the long-term unemployed population in American

cities, tenaciously persists in academic and policy circles. At the core of all dominant definitions, the term references an urban population that is persistently low income and has difficulty obtaining suitable waged work to ensure a decent quality of life. Most also agree that there is a strong racial and class association that corresponds to this population—that is, they are disproportionately African American, Latino, and workers at the lowest end of the new postindustrial service economy. At the same time, this population is recognized as having relatively poor access to key goods and services, such as decent jobs and housing, well-funded schools, and suitable parks and open space.

But much disagreement persists about the urban underclass concept. First, scholars clash over the reasons behind the deployment and resonance of the notion. On the one hand, it is suggested that the term *urban underclass* is a simple, objective, and neutral descriptor for a stratum of the impoverished urban population. It supposedly helps clarify the specifics of a particular needy, service-dependent population. Analysts here dispassionately put truth and reality into an accurate, descriptive term. On the other hand, others explain the term's origin and longevity in its ability to target and stigmatize a population. Analysts here are said to contribute to a complex societal process whereby the poor (and particularly impoverished ethnic minorities) become singled out and differentiated as culturally problematic beings in need of social rehabilitation. Analysts, in the process, wittingly and unwittingly validate a pejorative “classing” and “racing” of society that pervades public thought. In the debate over the use and resonance of the urban underclass concept, these two contrasting positions dominate.

Scholars also differ on the causes for the rise and persistence of this population. Staking out a widely accepted notion, William Julius Wilson explains this phenomenon by reference to a changed city, national, and international economy. Wilson and adherents identify the rise of a service-based economy (supplanting a manufacturing economy) that has afflicted the poor, particularly impoverished minorities. This rise of service jobs, concentrating in two areas—low-wage, “McDonald's-type” jobs and high-wage,

education-intensive jobs—fails to provide meaningful employment opportunities for this population. Concomitant with the loss of decent-paying manufacturing jobs, the working-class and poor populations get devastated. Unlike Wilson and his adherents, a group of Marxist scholars have sought to explain the reasons for this economic transformation. David Harvey traces this economic transformation to the rise of two forces, neoliberalization and globalization. First, new labor-punishing rules and regulations and corporate labor-cutting practices across America have allowed unskilled, low-wage, dead-end jobs to proliferate. Second, a new global reality has dramatically shrunk the globe. In the process, a hypermobility allows production units to close or move an accelerated number of manufacturing plants out of America to lower-wage world regions.

This position contrasts with the still entrenched notion of the culture of poverty. This alternative, coalescing around the ideas of Ken Auletta, George Gilder, and Charles Murray attributes the origin of the urban underclass to the emergence of an antisocietal culture in inner cities. The rise of counternormative values, manifest in “underclass behavior,” purportedly send inner-city mothers, fathers, and children down paths of social dysfunction, with an inability to integrate into mainstream America. One structural factor is seen by many in this camp to shape this population: the individually damaging effects of a dysfunctional welfare state apparatus that ran roughshod over this population, beginning in the 1960s. Government programs inadvertently killed individual initiative to work and sacrifice, creating a service-dependent population now enslaved to government largesse.

Scholars also disagree on the duration of existence of this population. To some, a distinctive, new urban underclass is less than 30 years old. Its roots are in the post-1980 ascendancy of the postindustrial economy, which has dramatically polarized the rich and poor in urban America. This position notes a long history of poverty, underemployment, and unemployment in U.S. cities. However, they point to a relatively new reality of long-term poverty populations having grown more hopeless, despairing, and socially removed from society’s mainstream. In contrast, others see the contemporary urban underclass

population as simply the most recent manifestation of a long-term urban poverty population. There roots have been variously traced to the supposed afflicting effects of the Great Society in the 1960s, the Keynesian economic stimulus apparatus beginning in the 1930s, and the “reality” that the poor have always been with us and will always be with us as long as people have different wills and initiatives to succeed.

Finally, scholars disagree on the level and intensity of the constraints that impinge on the daily lives of this population. Two dominant positions have arisen. The first contends that the black urban underclass reflects a legacy of historical discrimination that pervasively persists today. Some writers fervently argue that African Americans have faced discrimination in housing markets, labor markets, and common social life that superseded that of other previous ethnic populations in cities. In this context, they suggest that blacks today continue to be held back in labor hiring practices, job promotion opportunities, obtaining better housing, and securing government services. Paraphrasing Cornel West, hiring, firing, and everyday life in cities today is still profoundly colored. But other voices proclaim such discrimination as essentially dead. Racism is said to persist in withered, subtle ways, but the reality of an urban underclass now must be explained by other factors, namely, human choices embedded in a ghetto cultural formation. Poverty and isolation are supposedly now normative, the end products of human decision flowing out of the structure of poor black communities. Poor blacks have absorbed and re-created an oppositional culture—that is, a set of behaviors, attitudes, and expectations that fundamentally conflict with those of the broader society.

The urban underclass concept today takes on more salience as poverty has deepened and really expanded across American cities. Yet scholars are no closer to resolving their differences of opinion about this notion’s *raison d’être*, the rise and causes of this referenced population, and the duration of its existence. After years of national silence regarding urban poverty, the controversy over the notion of urban underclass is likely to intensify.

providing water of sufficient quantity and quality to urban populations is significant. Demand for water is driven by population growth and changes in the ways in which societies demand water for domestic, industrial, and commercial uses. Providing water to urban settlements has involved technological and engineering innovation. Deeper, and often controversial, struggles over access to and control of water are also important. These institutional and political questions are rarely resolved in a consistent manner and reveal deep contradictions. Many of these involve conditions of scarcity. This scarcity, even though it may have origins in physical conditions, is often not natural. Instead, scarcity is the result of power relations that have evolved in particular places and times. Rapid urbanization, whatever the timing or cause, lays bare the complexities of urban water supply. Opening with a brief examination of the technical aspects of supplying water to urban areas, this entry provides a consideration of systematic inequities in access to water in both historical and contemporary contexts.

Technology, Engineering, and Urbanization

Ancient engineering techniques for moving water for domestic purposes displayed keen engineering skill in using gravity. Innovations included the use of natural and manufactured pipes, containers, and taps and the use of various simple machines. The Roman aqueducts, for example, moved large quantities of water over long distances and efficiently and elegantly stored and distributed water within cities. Other ancient and medieval societies similarly mastered the use of gravity, with varying degrees of precision.

Bringing water to a city allowed both private and public uses. In addition to meeting practical needs, many of these uses were symbolic and served to reinforce or legitimate sets of power relations. Even in medieval Europe, regarded as a period of technological reversal and stagnation, the exploitation of water sources outside cities and the construction of water conduits continued. In this case, it was often through the exercise of the ecclesiastical power of the Church rather than the secular power of government. Expertise in gravity-based techniques diffused from city to city or from monastery to monastery. Adoption,

URBAN WATER SUPPLY

Water and cities have a complex relationship influenced by natural conditions and by the abilities of human societies to adapt and reshape them to meet their needs and desires. The challenge of

however, was uneven, and even with adoption, place-based particularities influenced access to water and the types of uses made of it—for example, open fountains in Italy or spigots in England.

Cities and towns with ample local water supplies or proven long-distance access to them sometimes enjoyed a comparative advantage as manufacturing and later industrialization took hold. In cities that experienced rapid population growth in the manufacturing era, adequate potable water supplies became a necessity. Demands for potable water supplies in the largest cities were driven by concerns over public health, as human and industrial waste had compromised available local supplies. It had become clear that piecemeal private provision of water was insufficient to protect the rich and powerful against the threats of waterborne diseases. Responding to both elite demands and the pressure of broader political movements, collective and most often public ownership and operation of urban water emerged. Success in the development of water and sewerage services dramatically reduced the impact of waterborne diseases. Rapid growth required significant additions to the water resources of cities, particularly if the available local resources were limited or too polluted for use.

In the North American context, New York City extended its influence (using state authority) into a widening hydrological hinterland. As in ancient times, the city and the countryside became linked through this hydrological connection—faster growth and greater water demands led to the expansion of what some have called the “water frontier.” For modern-day New York, this means a network of reservoirs outside the city, with city influence on land use and environmental change. More than 1 billion gallons of water is delivered daily.

Similar stories can be told about most major cities in the core of the world economy as they added publicly provided water supplies. In areas of extreme water scarcity, limits on water supply could constrain population and economic growth and required more aggressive and long-distance appropriation. These, in turn, have prompted conflict as rural demands for water, especially for agriculture, have been displaced by thirsty cities and the perceived inevitability of urban and suburban growth.

Water treatment to achieve an aesthetically acceptable or healthier product has similarly evolved. Techniques have grown from rudimentary settling chambers and sand filters designed to improve the smell and appearance of water to the addition of chemicals and more advanced purification techniques targeted at bacteria, viruses, and parasites. Cities increasingly have come to rely on a complex combination of engineering and chemistry to meet everyday water needs. A failure of these technologies can quickly lead to public health threats.

Geographical and technological fixes for urban water problems require tremendous commitments of resources. In the modern setting, water infrastructure requires significant initial financial investment as well as a commitment to maintenance over the longer term. In the United States, water borrowing by cities to provide for water and sanitation needs grew exponentially in the late 19th century. Urban areas outside the core of the world economy, particularly capital cities and those with an industrial base, also added public water systems. Sometimes, improvements were seen to have significant symbolic value, providing the appearance of modernity as well as health benefits—even if only for a fraction of the city and its population.

Organizing Water Delivery

The construction and operation of urban water systems does not mean that all residents of a city receive water of consistent quality and quantity. Indeed, inequities in water delivery and pricing were and are commonplace and remain a structural feature of many urban landscapes. This is partly because of the reactive nature of water supply provision (supply capacity lags behind demand), but systemic inequity is also an outcome of place-based power relations and, therefore, is of special interest to geographers. These inequities were present in ancient societies and remain visible today. The formal architecture of political power in a state plays a significant role in the development of urban water supplies by influencing the geographical scale for responsibility. Countries with strong central governments have different planning and implementation processes than those where power may be devolved

to the regional or local scale. Rigorously enforced national environmental or drinking water standards with strong fiscal support will bring results that are vastly different from those where local decision making is coupled with limited access to capital.

In many cities, increases in population outstrip existing or planned capacity. This is true whether population increases are caused by 19th-century industrialization and urbanization or 21st-century migration from the countryside into shantytowns or informal neighborhoods in countries in the periphery of the world economy. Individual areas within a city may have water service as a consequence of local political movements or simply because of political patronage. On the other hand, they may *not* be served because of lack of political power, to prevent temporary settlements becoming permanent, or to avoid unacceptable compromises of service to other, “more deserving” areas. Residents of areas that lack a reliable supply of good-quality piped water, even at the scale of shared public standpipes, are forced to rely on their own wells or surface water or other methods of provision. Lack of sanitation and the presence of industrial pollution may make wells or surface water unhealthy, leading to higher child and infant mortality rates and shortened life expectancies. Those with no other choices may also be subject to the market relations of vendors, who may get water from a public system only to sell the water under exploitive and monopolistic conditions. This situation, sometimes facilitated and supported by urban politics, can lead to egregious exploitation through the regressive pricing of urban water. Poor and marginalized populations often get less water at lower quality and yet pay significantly more for it. Water provided by public systems may be influenced by collective ideals, public subsidies, and the regulation of a “natural monopoly.” Those excluded from the public supply experience no such protection.

The keystone status of clean water in public health and economic development has drawn consistent attention in international development policy. The 1980s, for example, was declared the International Drinking Water Supply and Sanitation Decade by the United Nations (UN). Water and sanitation feature prominently in Earth Summit (United Nations Conference on Environment

and Development, 1992, Rio de Janeiro) documents such as Agenda 21 and in the UN Millennium Development Goals. The 2006 report of the United Nations Development Programme specifically focused on water and sanitation, providing further compelling analysis of water problems.

The practicalities of meeting the water needs of millions of people have involved shifting institutional and organizational arrangements. While there may be limited room for optimism, the situation is complex and laden with contradiction.

Contemporary Political Economies of Water

Recent conflicts have stemmed from the impact of globalization. Here, a neoliberal agenda of commodification and privatization runs head-on into visions of water as a collective human right. In the context of globalization, policy-based lending from the World Bank and International Monetary Fund has brought the realities of global capitalism and corporate control into the arena of urban water supply. Defining water as an economic good (as well as a necessity) became fused with a vision of private expertise as the best solution for urban water supply woes in the developing world. This expertise was to be provided by global corporations—with attractive, and often guaranteed, returns on their investments—themselves funded with loans from the World Bank or other multilateral lenders. The privatization message took on an almost magical allure and was backed by the financial power and dominance of global institutions and corporate interests. This showed itself in different ways in different settings, with impacts in all world regions. In England and Wales, for example, privatization was a response to a domestic policy agenda (deregulation and privatization of government enterprises) and the financial pressures of compliance with European Union environmental directives. In France, private companies, which have played a significant role in water services for decades, became global-scale operators through mergers and acquisitions. In the United States, where municipalities with aging infrastructure and underinvestment faced massive financial commitments, international corporations offered the promise of better service for lower costs as well as a reduction and “disciplining” of the

public sector workforce. In the cities of the developing world, policy-based loans, often as part of national-scale structural adjustment packages, have transformed the provision of urban water by requiring privatization. Global-scale water corporations have received lucrative concessions and contracts with promises not only to meet ambitious collective water supply goals but also to fully recover their costs (and profits). Global privatization has been paralleled by the development of global-scale governance. This has occurred not only through existing international institutions but also through the creation of new organizational forms, which are not state based but part of the development of a new international regime for water.

While privatization and commodification have been part of this international regime, there has also been resistance to privatization from international nongovernmental advocacy organizations, localized and global social movements, and public sector labor unions—a broader and globalized civil society. While outcomes have varied, there is one clear finding: Privatization and commodification have not been panaceas and have, in fact, moved the inequities of urban water provision into the public limelight. Urban water is no longer the domain of engineers and bureaucrats. It has become the focus of the mainline international environmental organizations, global corporations, global capital investment funds, national and international economic and social development organizations, investigative media, and an array of vocal advocates and activists for democracy and transparency. Place-based stories of protest and resistance, in print and on video, are not confined to the streets of cities in the developing world; they also feature in the city council chambers of North America. The details of each story may be different, but underlying each is a deep and enduring concern over access to and control of water.

As the 21st century unfolds, urban water provision promises to be at the cutting edge of local and global conflict. Conflict over the broader availability of water will be supplemented by struggles over the ways in which the provision of water is organized. Concerns over efficiency of urban water consumption as well as the risks of terrorist threats to the integrity of urban water

supplies have joined the list of controversies. Against a backdrop of climate change and evolving forms of global capitalism and civil society, urban water supply will continue to be a focus of examination.

USABILITY OF GEOSPATIAL INFORMATION

A number of possible definitions of usability are available in the literature of geospatial information, and the needs of spatial data usability have been compared and contrasted with the broader data-related activities of providers and users of

geoinformation. For example, one official definition of usability is given by the ISO 9241-11 standard on Display Screen Regulations, Use of Ergonomics for Procurement and Design. In this definition, system usability consists of the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use, where

- effectiveness measures the accuracy and completeness with which users achieve specified goals,
- efficiency measures the resources expended in relation to the accuracy and completeness with which users achieve goals, and
- satisfaction measures the freedom from discomfort and the positive attitudes toward the use of the product.

Usability elements outline the features and characteristics of the product that influence the learnability, effectiveness, efficiency, and satisfaction with which users can achieve specified goals in a particular environment. The context of use determines the types of users, tasks, and equipment and the physical and social environments in which a product is used. Therefore, a system consists of users (the people who interact with the products), equipment (hardware, software, and materials), tasks (activities required to achieve a goal), and a physical and social environment for the purpose of achieving particular goals.

Usability has also been defined as a set of attributes that bear on the effort needed for use, and on the individual assessment of such use, by a stated or implied set of users (see ISO 9126). This definition differs from the ergonomics-based definition in that characteristics other than efficiency and effectiveness are also seen as elements of usability.

Nielsen, concerned with software usability, sketches a broader context he calls system acceptability. One aspect of it is usefulness, which pertains to whether the system can be used to achieve a desired goal. Therefore, it is possible to break usefulness down into utility and usability—utility denoting the question of whether the functionality of the system in principle can do what is needed and usability denoting the question of how well users can use this functionality.

It is hard to isolate a core set of fundamental techniques that clearly distinguish data usability from any single-component discipline; in some ways, it is a uniquely powerful combination of individual techniques that characterizes the field. In summary, data usability might be identified as an umbrella term consisting of several elements aggregated into several groups:

- *Marketing*: added value, benefits, costs, novelty, services provided, and satisfaction
- *Quality*: authoritativeness, guarantee against error, integrity, metadata, reliability, validity, and utility
- *Software and tools*: human computer interaction, standardization, integration, searchable, and interface
- *Human perception/cognition*: authoritativeness, decision type, interestingness, novelty, popularity, satisfaction, trust, user skill levels, familiarity, interpretation, and visualization
- *Applications*: aggregation levels, type, exclusiveness, visualization, integration, decision type, use with models and algorithms, availability, and accessibility

Each individual category can be discussed in light of specific user groups and/or applications. For example, in the marketing category, cost is a very common and often a very important element and plays a large part in usability. In the applications group, availability and accessibility also determine the use of data. Moreover, it is important to realize that elements such as accessibility and cost of spatial data can vary among different countries and cultures. Another example is the update frequency. To decide on the desired update frequency, users should be asked to define the tolerable difference between decisions made and the time frame for future decisions.

There is also a dynamic component in the definition of usability. As time goes by, some data sets will be more useful than others. This is a consequence of the nature of the elements being depicted and the temporal and spatial scale of the representations. Accordingly, consideration will have to be given to the best way of improving the use of the database. Again, a usability framework should provide milestones for the application of objective methods aiming to extend the lifespan

of a database within reasonable limits. This methodology will affect the way data sets are produced, maintained, and used. There is also considerable scope for the implementation of data-modeling techniques such as rule-based classifications and data mining.

Finally, there is an important element linked to the way users perceive and use existing data sets. The same data presented in an unfamiliar way to the user become ineffective. The human interface is an important area for constant improvement. Visualizations such as three-dimensional representations, virtual reality, and animations seem to bridge the gap between data producers and data consumers. Therefore, these techniques improve the likelihood of data being fully understood and used.

VAGUENESS IN SPATIAL DATA

This entry examines aspects of vagueness in spatial data from the perspective of a spatial database used to support a geographic information system (GIS). A spatial database is a collection of data concerning objects located in some reference space that attempts to model some enterprise in the real world. The real world abounds in uncertainty, and any attempt to model aspects of the world should include some mechanism for incorporating uncertainty. There may be uncertainty in the understanding of the enterprise or in the quality or meaning of the data. There may be uncertainty in the model, which leads to uncertainty in entities or the attributes describing them. And at a higher level, there may be uncertainty about the level of uncertainty prevalent in the various aspects of a database.

Many operations are applied to spatial data under the assumption that features, attributes, and their relationships have been specified a priori in a precise and exact manner. However, inexactness often exists in the positions of features and the assignment of attribute values and may be introduced at various stages of data compilation and database development. Models of uncertainty have been proposed for spatial information that incorporate ideas from natural-language processing, the value-of-information concept, non-monotonic logic and fuzzy set, and evidential and

probability theory. Thus, in the modern GIS, there is a need to more precisely model and represent the underlying uncertain spatial data. The major aspects of spatial data description to focus on for uncertainty considerations include spatial region descriptions, spatially related attributes, and spatial relationships.

Spatial Region Descriptions: Fuzzy Sets

In contrast to an ordinary set for which a set element is either in or out of the set (set membership of only 0 or 1), a fuzzy set is one in which the membership of an element may have a value between 0 and 1, representing the degree to which the element belongs to the fuzzy set. Within a fuzzy set, we may have objects comprising the *core* (full membership of 1.0 in the set in question), and we may have a *boundary* (the area beyond which they have no or negligible membership in the set). A classic spatial example of the core and boundary problem is determining where a forest begins. Is it determined based on a hard threshold of trees per hectare? This may be the boundary set by management policy, but it is likely not the natural definition. There are several ways to manage these uncertain boundaries. If a spatial database can represent the outlying trees as being partial members of the forest, then a decision maker will see these features as being partial members if the database is queried.

Spatially Related Properties

Next, consider spatially related properties such as soil types, which might be described in linguistic terms such as

{sandy, loamy, . . . }.

Such linguistic terms are commonly modeled as *fuzzy sets*. So soil classification might be assessed as belonging to the fuzzy set “sandy” with a membership value of 0.8. It is also possible to allow numeric as well as scalar values. For example, a fuzzy number such as “about 3 cm” of rainfall at a location could be used.

To use minimum bounding rectangles in a spatial database for vague regions, a fuzzy minimum bounding rectangle (FMBR) can be defined as consisting of nested rectangles. The innermost rectangle is the MBR over the core of the vague region (certain region or membership = 1). The outer rectangle is an MBR over the outer boundary of the vague region. This approach allows the consideration of common indexing approaches such as grid files or *R*-trees.

Spatial Relationships

The major types of spatial relationships that can be considered are geometrical orientation and topological relationships. An approach to uncertainty in such spatial relations can be based on determining configuration similarity for spatial constraints involving topology, direction, and distance. This approach uses extended objects for direction and topology, and centroids for distance; it handles uncertainty in fuzzy relations, for example, an object that satisfies more than one directional constraint, as well as fuzziness related to linguistic relationship terms. Another approach is based on MBR and spatial extensions of Allen’s temporal relationships. The basic relationship definitions, and their use in defining relevant directional and qualitative topological relationships, provide a framework for the abstract spatial graph, a spatial data structure specifically designed to retain orientation and topological information with respect to two-dimensional objects and to provide information to support fuzzy querying capabilities on these relationships. The weights

computed from the abstract spatial graphs directly support fuzzy queries regarding qualitative topological and directional information. These techniques permit queries such as “Does ‘some of Object A overlap most of Object B?’” or to determine that while Object A is *slightly southwest* of Object B, it is at the same time *mostly west* of Object B.

Another approach to representing uncertainty that can be used is the theory of rough sets. Rough sets involve a universe, U , and the indiscernibility relation, R upon U . Then, a rough set X is defined by

Lower approximation of
 $X: RX = \{x \in U \mid [x]_R \subseteq X\},$

Upper approximation of
 $X: \bar{R}X = \{x \in U \mid [x]_R \cap X \neq \emptyset\},$

where $[x]_R$ denotes the equivalence class of R containing x .

Consider the spatial concepts, $U = \{\text{tower, stream, creek, river, forest, woodland, pasture, meadow}\}$, and let R be as follows:

$R^* = \{[\text{tower}], [\text{stream, creek, river}], [\text{forest, woodland}], [\text{pasture, meadow}]\}.$

Given some set $X = \{\text{medium, small, little, tiny, big, huge}\}$, we would like to define it in terms of its lower and upper approximations:

$RX = \{\text{tower, stream, creek, river}\}$

and

$\bar{R}X = \{\text{tower, stream, creek, river, forest, woodland, pasture, meadow}\}.$

A *rough set in A* is the group of subsets of U with the same upper and lower approximations. In the example given, the rough set consists of the following subsets:

{tower, stream, creek, river, forest, pasture}

{tower, stream, creek, river, forest, meadow}

{tower, stream, creek, river, woodland, pasture}

{tower, stream, creek, river, woodland, meadow}.

The major rough set concepts of interest are the use of an indiscernibility relation to partition domains into equivalence classes and the concept of lower- and upper-approximation regions to allow the distinction between certain and possible, or partial, inclusion in a rough set.

The indiscernibility relation allows us to group items based on some definition of “equivalence” as it relates to the application domain. We may use this partitioning to increase or decrease the granularity of a domain, to group items together that are considered indiscernible for a given purpose, or to “bin” ordered domains into range groups. To allow *possible* results, in addition to the obvious, certain results encountered in querying an ordinary spatial database system, we may employ the use of the boundary region information in addition to that of the lower-approximation region. The results in the lower-approximation region are certain. These correspond to exact matches. The boundary region of the upper approximation contains those results that are possible, but not certain.

VANCE, JAMES (1925–1999)

James E. Vance Jr. is known for his scholarship on urban, historical, and transportation geography. These interests became apparent in his doctoral dissertation on *The Growth of Suburbanism West of Boston*, supervised by Raymond Murphy and completed at Clark University in 1952. After holding appointments at the Universities of Arkansas, Wyoming, and Nebraska, he taught from 1958 to 1991 at the University of California, Berkeley, where he directed 28 successful doctoral dissertations. His work emphasized the evolution and structure of cities; the roles of transportation and trade in shaping regional settlement; and the social processes that internally differentiate urban areas. Vance (1990) focused especially on “urban morphogenesis—the creation and subsequent transformation of city form” (p. 38).

The popularity of Vance’s courses on urban geography and transportation geography led him to write monumental textbooks on these subjects. *This Scene of Man* (1977) surveyed the evolving role and structure of the city in Western history. A revised edition, *The Continuing City* (1990), added two chapters on the modern metropolis and transportation innovations since 1850. In *Capturing the Horizon* (1986), Vance traced the emergence of modern transportation systems: canals, railroads, urban transport, maritime navigation, and aviation. His final book, *The North American Railroad* (1995), interpreted development of the railway networks of the United States and Canada, where, he argued, geographical factors dictated significant variations from British antecedents.

Vance made several influential contributions to geographic theory. First, in his work on the functional organization of the North American downtown, he argued that abstract economic forces such as land rent were insufficient to understand the structure of the central business district (CBD); instead, he stressed historic origins, functional requirements, and social factors. Vance summed up the historical-geographical processes of CBD evolution as “the seven lives of downtown: inception, exclusion, segregation, extension, replication and readjustment, redevelopment, and the city of realms.”

A second geographical contribution was the “mercantile model,” which highlighted the role of long-distance trading ties in locating early settlements around the port, transportation facilities, warehouses, markets, and so on. Intended as a critique of and alternative to Walter Christaller’s central place theory, Vance’s (1970, 1990) mercantile model argued that wholesale trade resulted in the formation of new settlements or “points of attachment,” which if successful became regional centers with their own hinterlands. This emphasis on commercial forces external to the local urban system, confirmed by empirical studies in North America, provided a missing link in central place theory.

A third contribution was the concept of “the city of realms,” an influential spatial model for the contemporary North American metropolis. Vance’s view of the urban-realm model recognized a decentralized metropolis split into a series of daily activity areas no longer dependent for their existence on the traditional CBD. The criteria of urban realms included topography and physical geography, the overall size of the metropolis, economic functions of the realms, and the regional geography of transportation. Vance’s (1977, 1990) “city of realms” predicted the contemporary dispersed metropolis a quarter century before notions of “edge cities” came into vogue.

VARENIUS (1622–1650)

Bernhard Varen (latinized to Varenius) was born near Lünenburg, Germany, in 1622. Through studies at the gymnasium of Hamburg and the University of Königsberg, he excelled in mathematics, natural science, and philosophy, leading to the completion of a degree in medicine at the University of Leiden in 1649. There is no evidence of his having practiced medicine. Rather, he settled in Amsterdam, working as a tutor and taking interest in the discoveries of contemporary Dutch navigators, the work of geographers, and the achievements of Willem Blaeu and other cartographers. Varenius contributed to regional understanding with *Descriptio Regni Japoniae* in 1649 and to studies of religion. However, he is best known for *Geographia Generalis*, published in the 28th and final year of his life by Elsevier Press in 1650.

Geographia Generalis is a milestone in the history of science, staking a position for a formal discipline of geography, aligning it with the rationalist perspective of the early Enlightenment (represented in the philosophies of René Descartes and Francis Bacon) and with the commitment to empirical documentation. Residing in Amsterdam, Varenius had access to the wealth of new information made available through seafaring voyages of discovery and trade. Documenting and systematizing that knowledge was one of his central objectives. He recorded quantitative information about the shape, size, and motions of Earth, documented findings about the distributions of land and water, and systematized notes on the characteristics of mountains, woods, deserts, and the atmosphere in different locations, seeking where possible to identify trends and general spatial patterns.

Geographia Generalis identifies two branches of geography—special and general. Whereas

special geography is focused on the description of countries and regions (referred to today as regional geography), general geography was seen by Varenius as a systematic science, focused on understanding the features at the surface of Earth and on relationships between Earth and other celestial bodies. He saw value in basing regional description on a foundation of general understanding and proceeded to outline three different aspects of general geography. These included absolute geography, to measure the size, shape, and motions of Earth; relative geography, to draw associations to climatic patterns and the measurement of time; and comparative geography, to describe geographical variations in the characteristics of different parts of Earth and to identify appropriate principles of mapping and navigation.

Historians of geography characterize the successive translations and revisions of *Geographia Generalis* (by Isaac Newton in 1672 and 1681 and by others well into the mid 1700s) as helping establish a foothold for teaching systematic geography in many of the leading academic institutions of Britain, America, and Europe. It provided a foundation for thinking about the practices of geography and its role in science. The work of Varenius was invoked in 17th- and 18th-century debates over the merits of Cartesian and the Newtonian scientific systems, lauded by Alexander von Humboldt in his *Cosmos*, and although it no longer garners such central attention, it is seen as a foundation for good scientific practice by 21st-century scholars who seek to advance the science of geographic information.

VECTORIZATION

Vectorization is the process of converting or transforming a scanned image or raster file by digitizing features into sets of X,Y coordinates and then using software to create a vector file or layers of points, lines, and polygons that represent corresponding features from the parent raster image. After vectorization, attribute data can be assigned to the points, lines, and polygons.

Vectorization is part of a larger set of tools within geographic information systems (GIS) software programs. Vectorized data can be used to study, learn, and make decisions about how humans interact with their surroundings, resources, other living things, or the larger environment.

In the early days of GIS, the process of vectorization was known by terms such as *raster-vector restructuring*, *line extraction*, and *line modeling*. Line modeling was also known as *spaghetti modeling*. This modeling represented line data in a very unstructured way, with the end result being a set of intertwined and disconnected lines that looked like a plate of spaghetti. As attribute data were added, lines with similar attributes were given the same symbology, and the lines began to fall into categories that had structure. These categories were then separated into different layers.

Vectorization is a basic component of GIS used in processing raster data to create various vector layers that make up the components of a GIS database. For example, if roads were traced or digitized using GIS software from an aerial photograph, the individual segments that make up the road, both curves and straight segments, would be turned into a series of X,Y coordinates to form corresponding line segments that represent the image of the road on the aerial photograph. These segments are then grouped together into a vector layer. The layer then represents the road in the GIS. This process is repeated for all other graphic elements from the air photo, which may include ponds, fields, parking lots, house locations, intersections, power poles, and so on and are then converted to vector point, line, and polygon layers. From these layers, attribute data can be attached describing all possible characteristics of the points, lines, and polygons that have been created. These vector layers can then be

used together with other geospatial data sets and layers in a GIS to perform spatial analysis.

VERNACULAR LANDSCAPES AS EXPRESSIONS OF ENVIRONMENTAL IDEAS

Vernacular landscapes, sometimes termed *ordinary landscapes*, are the surfaces of everyday life that we see all around us and that are created and re-created daily. Cultural geographers study vernacular landscapes to understand the lives of ordinary people who live in those landscapes. Ordinary landscapes take the form of everyday places such as parking lots, tree-shaded suburbs, trailer parks, or a patchwork of fields in Midwestern U.S. farmlands. They are lived in and are continuously changing.

Geographers agree that there are many layers of meanings embedded in any landscape and that multiple cultural landscapes exist in the same place. These vernacular landscapes can be studied to illuminate ideas about the human environment. However, the term *landscape* is somewhat ambiguous. Its meanings can be understood and even expressed differently by different social groups and at different times. It is used by many professionals, among them architects, artists, Earth scientists, geographers, and historians, with myriad meanings. Differences in meaning between disciplines and even within a discipline present challenges in understanding and translating the term. The landscape is all around us; it is related to

nature but is not identical with nature. Landscape is also related to the environment. It is less organic than the everyday environment that sustains and surrounds people, and also less inclusive. There is scenery in every landscape, but landscape is not identical with scenery. Geographers have described landscape as the intermingling of physical, biological, and cultural features.

Cultural geographers observe landscapes with their eyes but interpret them with their minds. Peirce Lewis has argued that landscapes are the products of impressions of our senses rather than the logic of sciences. Landscapes are expressions of cultural values, social behaviors, and individual actions worked into a particular locale over a span of time. Lewis has further maintained that the human landscape reflects human values and aspirations, tastes, and fears, combining them into a tangible, visible form. The landscape holds a fairly accurate cultural record, one that many cultural geographers agree is an unintended autobiography where glories are embedded and cultural warts and blemishes are also included. Grady Clay has said that there are no secrets in the landscape. The ordinary day-to-day qualities of people are exhibited for anyone who wants to find them and knows how to look for them.

Contemporary cultural geographers have created different categories of landscape types. The differences in the categories have to do with the elements contained in those landscapes. In addition to vernacular landscapes, there are symbolic landscapes, which are representations of specific virtues, values, ideas, or memories. For instance, a builder, artist, politician, and/or a financier can aspire to impart a particular idea to the larger public. The Lincoln Memorial and other public buildings and monuments around the Mall in Washington, D.C., were built in the neoclassical architectural style and were deliberately designed to communicate the grandeur and a sense of power. The Lincoln Memorial itself imitates the style of the Greek city-state and communicates the authority and power of democratic principles.

Ordinary landscapes influence and change the perceptions, values, and behaviors of the people who live and work in them. Since they are continuously changing and geographers cannot study everything, they study selected items in the ordinary, everyday landscapes; however, scholars

Tulip field in a typical Dutch setting, Berkmeer, the Netherlands

Source: Jaap Hart/iStockphoto.

must put them in context, where they are a part of a larger thing that is undergoing continuous modification and change as a result of both conscious as well as unconscious processes.

Two Examples of Vernacular Landscapes

Two examples illustrate vernacular landscapes. The first is the historic beginning of vernacular landscapes as described by John Brinckerhoff Jackson. The second example uses elements in the vernacular landscape of a community in southwest Uganda.

The term *vernacular* suggests something traditional, homemade, or countrified; historically, the term was associated with buildings. Identifying dwellings as vernacular alluded to the work of a

craftsman who used local materials and techniques, but the buildings also reflected local environmental and economic conditions. Jackson was one of the early geographers who traced the historical development of vernacular dwellings from their beginnings in European architecture of the 16th, 17th, and early 18th centuries. According to Jackson, the term *vernacular dwellings* was mostly used by architects and architectural historians to emphasize form and building techniques. Vernacular dwellings were seen as loyal to local forms and rarely incorporated external innovations; they were even considered timeless. A shift occurred in the mid 19th century as signaled by the exploration of rural life by antiquarians and others who sought a life beyond the urban, industrial one.

Later studies of the vernacular landscape involved archaeologists, geographers, and social historians, who brought to light the fact that the vernacular building was not timeless but had a history of its own, different from formal architecture yet shaped by ancient archetypes. The vernacular building, they argued, had undergone a long and complex evolution. During colonial times, the American vernacular dwelling, in both rural and urban locations, was movable or even temporary and focused on the child-centered family. This vernacular dwelling has evolved over time to include utilities and other conveniences and an increased number of rooms. Jackson suggested that the American vernacular dwelling, although designed as a micro-environment, greatly depends on the community. The vernacular dwelling is a source of services rather than a political entity. It has evolved in the suburbs, company or college towns, trailer parks, resort areas, and condominium complexes.

This second example describes two elements of the vernacular landscape of the Chiga community of southwest Uganda. The Chiga are mostly subsistence farmers who are increasingly focusing their energies on producing food for sale in produce markets surrounding their locale.

The Chiga landscape is characterized by rugged hills and steep-sided valleys cut deep by occasional streams and swamps. During the rainy season, the swamps flood and cut off entire areas from access to produce markets for extended periods of time. Individual villages build bridges, which provide access across the swamp at its shallowest points. The bridges are unlike conventional bridges as commonly understood. Instead, they appear like an unsurfaced or dirt road with concrete pillars on either side. The pillars are about 3 ft. (feet) wide, erected upright to about waist height and about 12 to 15 ft. apart. Beyond the concrete pillars are deep trenches designed to drain the water away from the bridge surface. At one end of the bridge is a barricade designed to stop vehicular traffic while allowing foot traffic across. The community collects a small bridge toll to help with maintenance costs. A sign just before the bridge proudly declares the “floating bridge” open to traffic and includes the name of the community that built it and sometimes the date the bridge was opened for use. The concept of the floating bridge reflects the

fact that during the wet season, the swamp swells and covers the surface of the bridge, although one is always able to see the concrete pillars. Their portions above water appear to be floating and mark the limits of the hard surface of the bridge.

The hilly terrain with the steep-sided valleys makes it impossible to use mechanized farming techniques. Much of the land is cultivated by hand. The Chiga community is densely populated, and land parcels come in relatively small sizes. At a glance, the terrain has a terraced appearance, although terracing is not a technique that the Chiga employ. Instead, the land parcels are divided into horizontal layers as one travels downhill. The land has a patchwork appearance that comes from the various landowners making different land use decisions. Some fields lie fallow; some have crops that are browning as they near harvest season; and some have newly planted rows of sweet potato vines. Still other parcels appear forested as a result of having lost the fertile top soil to persistent soil erosion.

These two examples illustrate the ordinary nature of vernacular landscapes. They are lived in and created through a combination of conscious and unconscious processes. Vernacular landscapes are all around us and are undergoing transformation continuously. Studying them enables us to say something about the values, aspirations, tastes, fears, glories, and blemishes of the people who lived and continue to live in these vernacular landscapes.

VIA CAMPESINA (INTERNATIONAL FARMERS' MOVEMENT)

La Via Campesina has evolved as an international movement of poor peasants and small farmers from the global South and North. Initiated by Central, South, and North American peasant and farmers' movements and European farmer's groups, Via Campesina was formally launched in 1993 in Mons, Belgium. Existing transnational networks of activists located in peasant movements and nongovernmental funding agencies in the North facilitated the earlier contacts between key national peasant movements, most of which had emerged already in the 1980s. By 2008, Via Campesina represents more than 150 (sub)national rural social movement organizations from 56 countries in Latin America and the Caribbean, North America, (Western) Europe, Asia, and Africa. Since its birth, Via Campesina's main agenda has been to defeat the forces of neoliberalism.

Transnational regional coalitions of agrarian movements have played a critical role in linking (sub)national movements together. The most organizationally robust and politically coherent regional alliances are those in Latin America and Europe. The most uneven, thin, and organizationally and politically fragile regional alliance is the one in Africa. There are no regional networks of Via Campesina in the Middle East and North African region, Central Asia, the USSR, or China. One of the earliest regional pillars of Via Campesina was the Central American peasant alliance ASOCODE (Asociación de Organizaciones Campesinas Centro Americanas para la Cooperación y el Desarrollo), which was at its peak in the 1990s.

The entry of Via Campesina into the global governance scene has altered the international civil society terrain in many significant ways. For one, it has ended the monopoly of the International Federation of Agricultural Producers (IFAP) in terms of representing the farming sector in international governance processes. Founded in 1946, IFAP is an international farmer's federation of generally medium to rich farmers. Via

Campesina's entry provided a distinct representation for poor peasants and small farmers. Moreover, Via Campesina's entry into the global scene ended the monopoly of nongovernmental organizations (NGOs) in representing "civil society" in various state and nonstate fora. Via Campesina is distinct in the sense that it is a movement that directly represents (sub)national organizations of poor peasants and small farmers in contrast to the intermediary role of NGOs.

Many of the national movements that are leading members of Via Campesina have engaged in dramatic anticorporate actions, such as bulldozing a McDonald's fast-food shop in France, burning a Kentucky Fried Chicken outlet in Bengaluru, India, and uprooting a genetically modified (GM) soya farm and a eucalyptus nursery in Brazil, among others. The protest suicide of Lee Kyang Hae, a South Korean farmer, during the Cancún World Trade Organization (WTO) negotiations was another form of dramatic action.

Via Campesina's political work focuses on seven issues:

1. Agrarian reform
2. Biodiversity and genetic resources
3. Food sovereignty and trade
4. Women
5. Human rights
6. Migrations and rural workers
7. Sustainable peasant agriculture

However, actual global campaigns have been highly uneven between these issues.

The campaigns against GM crops and the WTO are perhaps the most high profile among all Via Campesina's campaigns. Their campaign against GM crops is anchored by several high-profile national initiatives, especially in France (by the Confederation of French Farmers, led by José Bové), India (by the Karnataka State Farmers' Association, led by M. S. Nanjundaswamy, who died in early 2004), and Brazil (by the Movimento dos Trabalhadores Rurais sem Terra or MST, led by Joao Stedile). This campaign is framed within anticorporate monopoly and anti-monocropping practice perspectives. Meanwhile,

the anti-WTO campaign put Via Campesina in the global media spotlight from Seattle to Cancún to Hong Kong. Via Campesina was perhaps the most consistent and organized transnational agrarian movement that opposed the WTO.

The global campaign on agrarian reform by Via Campesina perhaps comes far behind in terms of global projection and impact. This campaign was launched in 1999, together with two other transnational civil society networks—Foodfirst Information and Action Network and the Land Research and Action Network. It was primarily a campaign against the neoliberal land reform framed and promoted by the World Bank. This policy promotes a land reform that is voluntary and based on the willing seller/willing buyer principle. It has been carried out in various countries, including Colombia, Brazil, South Africa, and the Philippines. While Via Campesina has been able to push the World Bank to a defensive political position on this issue, the general impact of the campaign at the national level has been marginal; the same policy was expanded in Brazil, and it remains the main national legal framework for South African land reform.

Meanwhile, campaigns on human rights have been intermittent. It has been limited to occasional global “action alert” calls for specific human rights violations in different countries. However, the Via Campesina campaign for a universal “Peasants’ Charter” can also be located within human rights, especially since this issue is being addressed before the United Nations Commission on Human Rights. There are no significant initiatives in the other areas listed earlier. Finally, since the Bali conference on climate change in December 2007, Via Campesina has identified climate change as a key transnational campaign issue. The group has attempted to address agrofuels and the food price crisis that erupted in 2008 as part of its broader campaign. Whether or not Via Campesina will be able to develop the climate change issue as a master frame in its transnational political campaign remains to be seen.

Moreover, Via Campesina is a transnational movement that goes beyond engagement in “expose and oppose,” agitation-propaganda types of campaigns alone. Via Campesina is seriously engaged in developing concrete alternatives and proposals. The main framework for its “catch-all”

alternative is the notion of food sovereignty—the right to produce, trade, and consume food within and near one’s territory. This alternative framework brings in several new key development issues that are related to geography, including the question of place or territory as well as scale. But it has also brought in old development questions, including rural-versus-urban, as well as industrial-versus-agricultural paradigms.

VIDAL DE LA BLACHE, PAUL (1845–1918)

Paul Vidal de la Blache is an important figure in the history of geography. Born in the village of Pezenas in the south of France in 1845, educated at the Lycée Charlemagne and the prestigious École Normale Supérieure in Paris, Vidal took the lead in establishing a French school of geography at the turn of the 20th century that became world renowned for its holistic study of landscape. Vidal held positions at the University of Nancy (1872–1877) and the École Normale

Supérieure (1877–1898), and was chair of geography at the Université de Paris, Sorbonne, from 1898 until his retirement in 1909.

Throughout his career, Vidal sought to establish geography as an explanatory science instead of the descriptive, almanac-style fact-finding exercise that most geographers of his time practiced. Having been thoroughly schooled in history, he also emphasized the human aspects of geographical study at a time when geographers usually paid singular attention to the physical environment. Vidal emphasized that existing geographical landscapes are the result of a combination of human and natural processes. As he put it, landscapes should be considered like “medallions,” forged with the image of the social ways of life they include. Nature does not determine social behavior, and social behavior does not fully dominate nature. Rather, social behavior adapts to nature’s constraints and opportunities in the production of what some now call *social-nature*. In geography, this became known as *possibilism*.

The scientific task of geography is thus to explain how the various landscapes that geographers observe actually evolved as a result of the different ways in which humans adapted to nature in different times and places. To study these various modes of life (*genres de vie*) in turn necessitates a holistic approach, including both social and natural science. To Vidal, this was precisely the synthesis that geography as a discipline should achieve, thereby distinguishing it from the more analytic disciplines of either society or nature.

To establish this new scientific geography, Vidal helped found a new research journal, *Annales de Géographie*, in 1891. This journal promoted holistic, interdisciplinary research on geographical landscapes and was dominated by the Vidalian approach, as was French geography until World War I. While critics questioned whether the notion of *genres de vie* could be used in the study of more urban, industrialized landscapes, Vidal’s approach was instrumental in the formation of the now famous French Annales School of History, influential for its equally holistic emphasis on the *longue durée* of human-environmental adaptation in the course of history. Indeed, because most French geographers refused to engage in the disciplinary turf battles at the turn of the 20th century, *la tradition vidalienne* was largely relinquished to historians (as well as Durkheimian

sociologists). As a result, soon after Vidal, French geography largely lost its focus and prominence both in France and elsewhere, and his role in the formation of these more successful disciplines is largely ignored.

VIDEO GAMES, GEOGRAPHY AND

Video games have only recently attracted attention from human geographers. Unlike other forms of popular media such as cinema, literature, or television, video games offer a highly interactive and experiential virtual world. It is this “worldhood” or “spatiality” that is an attractive and fertile research ground for geographers. Embedded within each video game is a particular world that the player is able to manipulate and explore. These worlds can be realistic or a complete fantasy, as in many role-playing games. A virtual world or space is often necessary to limit and frame the activities possible within a game. For example, it would be difficult to program or code for a game in which absolutely anything were possible. In this sense, video games are particular milieus of activity, often highly repetitive. A productive engagement with video games would elicit not only important textual, social, and political themes but also how the virtual worlds within video games are constructed, including the types of freedoms and choices they offer to the player, as well as the “perspective” used (such as third person or first person).

The history of video games goes back to the flight simulators widely used during World War II. In 1962, the very first video game, “Spacewar,” appeared. When Atari released the classic coin-operated *Pong* in 1972, video games started to become enormously popular. The introduction of the personal computer in the 1980s greatly enlarged the market for games played on machines such as the Atari 400 and the Commodore 64 and, later, Nintendo and Sega. Sony’s PlayStation took this industry to a new level. By the late 1990s, Web-based games allowed for the creation of massively multiplayer online role-playing games, such as “World of Warcraft,” connecting millions of players worldwide via the Internet.

The video games industry is lucrative and expanding at an unprecedented rate. Two thirds of U.S. households play them regularly. In terms of annual sales, it now rivals the Hollywood film industry. Indeed, in recent years the mainstream status of video games has been confirmed with huge releases such as the highly anticipated and critically acclaimed “Grand Theft Auto IV.” During the first week of its April 2008 launch, the game grossed more than \$500 million, smashing all previous video game and Hollywood records. Competitive video game events, once limited to a few networked computers in a basement, are now international events, such as the World Cyber Games. More surprising is that the average age of a video game player is currently 35 years, and she or he has been playing for more than 12 years according to the Entertainment Software Association.

The geography of the video game industry is an interesting and hybrid one, with the main centers of design and programming situated in North America, Japan, and Western Europe. This tri-regional structuring of the industry often leads to hegemonic representations but can also lead to blurred cultural and national identities. In the case of the former, video games that depict “wars” often do so from a narrow and single perspective. Games such as the hugely popular “Call of Duty” can be criticized for depicting simplified and racist enemies and allies. The hypersexual and hyper-violent content of video games is also a perennial source of controversy, although there is no clear consensus in the psychology literature on the impact that video games have on players. In this sense, video games are sites of ongoing culture

wars. Yet despite these overcoded representations, there is always the possibility of experimentation within video games. Online games such as “World of Warcraft” allow users to “perform” alternate gender identities. In summary then, video games allow players to interact in virtual worlds that “spatialize” the social, political, and sexual dimensions we find in everyday life.

VIEWSHED ANALYSIS

Viewshed analysis, a form of visibility analysis that identifies visibility between points in a landscape, emerged as a geographic field several decades ago. Recent advances in software and computing power enabled viewshed analysis to become a common form of geographical analysis, and it is now a standard tool in many geographic

Figure 1 Sample viewshed

Source: Author.

information systems, enabling viewshed analysis to be used in a range of fields. The following entry discusses the techniques used to calculate and analyze viewsheds as well as the applications of viewshed analysis.

Viewshed analysis is typically conducted as a raster-based operation in a GIS. It begins with the calculation of a viewshed, a two-dimensional (2D) projection of a view, using one of many algorithms (see DeFloriani & Magillo, 2003). The viewshed procedure identifies landscape areas that are visible from a given location based on elevations from a digital terrain model (e.g., digital elevation model, triangulated irregular network) and accounting for that location's height and position,

the view angle, and, frequently, a viewer height offset or maximum-view radius. Locations that connect to the observation location by a line-of-sight are identified as visible and part of the observation location's viewshed, while all other locations are not. The resulting viewshed thus approximates the view from a given location (Figure 1).

The structure of calculated viewsheds is analyzed using metrics that quantify viewshed characteristics. Numerous viewshed metrics exist and include measures of size, complexity, and relief as well as the visual prominence of landscape features of interest. Viewsheds for an observation point may be calculated under different land use scenarios and their metrics compared to assess

the impacts of proposed land use changes on scenic quality. Viewsheds may also be visualized and compared in three dimensions using 3D modeling techniques.

A variety of fields use viewshed analysis. In planning, it is often used to identify the potential scenic impact of proposed landscape changes (e.g., van der Horst, 2006). Viewshed analysis is also used to identify the economic values of different view types using economic valuation techniques (e.g., Bastian, Reiners, Blasko, McLeod, & Germino, 2002). Additionally, archaeologists employ viewshed analysis to reconstruct past landscapes or cultural interactions (e.g., Lake & Woodman, 2003).

VIRILIO, PAUL (1932–)

An important, if little understood, theorist of social and spatial change is Paul Virilio—the so-called high priest of speed, a planner, a historian of technology, a photographer, and a philosopher of architecture and cinema. Other than military

service, his formal education included the study of art at the École des Métiers d'Art as well as phenomenology at the Sorbonne.

Impressed by the events of World War II, Virilio's work is grounded in the practices of the military, and he regards the culture of speed as driven primarily by its needs, whose conquest of the tyranny of distance extends repeatedly into civilian life. Virilio takes as his point of departure the intersections of military technology and the experience of speed, underscoring the machinic qualities of time and space as they are produced and conceptualized through his central concern, war. Thus, the state is essentially a machine to wage war, exhibiting a logic quite different from the Marxist emphasis on capital accumulation; in Virilio's reading, the state is a “means of destruction,” not a means of production. For him, geography is a product of warfare because the preparation for and engagement in military conflict, including things such as logistics, intelligence, and the speeds of military machinery and rockets, are the fundamental bases of territorial organization. Space here is reduced to little more than a theater of war, and the state is simply a machine for waging it. Steady improvements in the ability to wage war are thus instrumental in developing the ability to bind together ever-larger units of space and time. Not capital accumulation but the dynamics of military conquest are the driving force behind the historical rounds of time-space compression. Space and time are the products of speed as it emanates from the prerequisites of warfare. Thus, Virilio asserts that

War and the preparation for it produce the space-time of human experience as a function of projectile speeds, logistical rates of transport, or intelligence insight gathering. The territorial organization of space into human settlements and political units of authority, from the earliest human village settlements to medieval city-states, modern nation-states and world-wide empires, reveals a constant tendency: they express different orders of military power, knowledge and technological organization. (1995, p. 365)

Telecommunications also figure centrally in Virilio's worldview, in which digital technologies

produced a world in which information is speed and duration is nonexistent. Virilio maintains,

Speed enables you to see. It does not simply allow you to arrive at your destination more quickly, rather it enables you to see and foresee. . . . Speed changes the world vision. In the nineteenth century, with photography and cinema, world vision became “objective.” . . . It can be said that today, vision is becoming “teleobjective.” That is to say that television and multimedia are collapsing the close shots of time and space as a photograph collapses the horizon in the telephotographic lens. (qtd. in Redhead, 2004, p. 45)

The tyranny of constant speed leads to alienated, stressed-out, exhausted citizens who populate the virtual geographies of the space of flows; distorts human perception; sterilizes communications; forces a colonialism of daily life by machines; and generates a mindless automation that robs people of their humanity in a hypermotorized, digitized world. Virilio asserts that time-space compression has become sufficiently complete so that the struggle for space—geopolitics—has been displaced by chronopolitics, the struggle for time. In Virilio’s view, postmodern capitalism has created such enormous time-space compression that “distinctions of here and there no longer mean anything” (1991, p. 13). Despite the hyperbole, Virilio’s insights are useful in understanding that speed and velocity are not simply technical issues but profoundly cultural and political ones as well.

VIRTUAL AND IMMERSIVE ENVIRONMENTS

A virtual environment is a setting that is not real but includes real traits with which people can identify. The contents may reflect pure imagination or may model the real world. The environment becomes immersive when users are no longer observers but participants in the setting that is depicted, in some cases becoming actors in a larger drama. This entry describes the nature of some of the most popular virtual environments, such as *Second Life*, and explores their significance for geography.

Virtual settings or environments have long been a part of the human experience, as exemplified by prehistoric cave paintings, the utopic “Garden of Eden” and “New Jerusalem,” Homer’s *Odyssey*, and the Greek and Roman “Golden Age” myths. Today, people lose themselves in the elaborate landscapes of movies, plays, and novels. And of course, there is the ever-present video game—the ultimate “out-of-body” experience for devotees. Geographers create their own virtual settings in the forms of maps, geographic information systems, and three-dimensional (3D) flythroughs.

Perhaps the most elaborate virtual environment is the virtual world, which emphasizes participant immersion and community engagement. While that books, movies, and plays invite the reader or viewer to step into imagined worlds, as do 3D renderings of landscapes, these types of immersion lack the “authenticity” of the virtual worlds that began to appear in the mid 1990s. Thanks to improving computer technologies (particularly in

gaming), and to the development of social networking and 3D Internet technologies, 21st-century virtual worlds are fully contained immersive environments in which participants not only imagine their involvement but are actually involved. Modern virtual worlds contain communities of people who interact in settings that are networked, persistent, synchronous, immersive, and, above all, 3D. Participants enter these worlds as extensions of, or alternatives to, the real worlds that they inhabit and the real lives that they lead.

The new virtual worlds are here to stay. The Gartner research group predicted in 2007 that by the end of 2011, 80% of active Internet users (and Fortune 500 companies) will have some sort of 3D presence. Other observers have commented that virtual worlds will soon be pervasive interfaces for the Internet, using multiple entry and exit points, and that “metaverse browsers” will connect participants to multiple worlds. According to Wade Roush, the user may encounter an “interverse” connecting various “intraverses.” In brief, virtual worlds offer the potential of redefining the communications landscape very much like the World Wide Web did in the mid 1990s.

The Nature of Virtual Worlds

The casual observer can be forgiven for his or her confusion over the multiplicity of terms associated with virtual worlds—for example, “synthetic” worlds, MMORPGs (massively multiplayer online role-playing game), MUGs (multi-user game), and, direct from Neal Stephenson’s 1992 Cyberpunk classic *Snow Crash*, the “Metaverse.” To some degree, they all refer to the same phenomenon. The commercial manifestations of these worlds include *There.com*, *Entropia*, *Active Worlds*, *Sims Online*, *Kaneva*, *Google Lively*, *Wonderland*, *Croquet*, and the increasingly popular (and occasionally infamous) *Second Life*. These platforms are not intended as games. There are no contest rules and no winners or losers. Instead, participants enter these worlds in search of friendships, to interact with professional colleagues, to establish businesses, to create organizations, and, in some rare cases, to earn large amounts of real money.

Second Life has monopolized recent press coverage and is the industry leader in terms of money

generated, number of “residents” (more than 14.6 million as of this writing), and graphics sophistication. At the heart of *Second Life* is the resident or character, called an *avatar*. Avatars can be modified in an almost infinite number of ways, including by race, gender, age, hairstyle, body mass, and even fashion sense. Some participants create avatars that are extensions of themselves—that is, to augment their true lives—while others construct new and (sometimes radically) different identities. Many participants generate multiple avatars to adopt different identity profiles for different occasions. In some cases, avatar creation is an attempt at therapy, as with the person confined to a wheelchair in real life who creates a walking character. Once in *Second Life*, residents may convert dollars into lindens, the *Second Life* currency, to buy clothing, new skins and shapes for their avatars, real estate, furnishings, and entertainment. Participants inside this virtual world interact with each other very much like they do in the real world, except that knowing who is really behind the wheel may be a mystery.

The geography of *Second Life* is complex and at times chaotic. The basic unit is the island or “sim” (as in “simulation”), which is a 256-m (meter) by 256-m grid embracing about 16 acres. Some of these units have been clustered to create corporate-controlled continents, of which there are perhaps half a dozen. The 21,973 islands (as of July 2008) are normally privately controlled. Islands and continents are placed to accommodate computer server needs, rather than natural processes, and are spaced in a very predictable gridlike sequence. This lack of regard for natural landform creation processes will cause consternation among geographers and geologists who look at the systemwide map. At the local level, however, terrain can be shaped to create mountains, shorelines, water courses, and so on, which, if done correctly, creates greater authenticity. Residents buy or rent real estate on these lands. Since there are no meaningful land use controls on the continents, they tend to be cluttered with garish builds that give the landscape a cartoonish quality. Private island covenants, on the other hand, prevent some of these excesses.

Three-dimensional social worlds such as *Second Life* are not without problems. Some users lament the complexity involved in learning how to

engage a virtual world, and almost everybody complains about platform stability. Avatars, as of this writing, do not show meaningful human expressions unless complex scripting is used. The social side of *Second Life* can be X-rated and off-putting to residents who stumble into the wrong location. *Second Life* is a user-created world with few rules.

Virtual worlds, and particularly *Second Life*, are increasingly being used by universities as meeting places and as a way of extending the university's global reach. In addition, some of the most beautifully constructed settings in *Second Life* are campuses, as illustrated by the University of Ohio and Vassar College sites. At Vassar, part of the Sistine Chapel has been meticulously re-created.

The Meaning of Geography

Virtual environments have long been the subjects of geographical inquiry, although relatively little work has been done on modern virtual worlds. It has been understood for some time, however, that once the technology matures, virtual worlds will become very much a part of the geographer's milieu (see the special edition on cyberspace of *The Geographical Review*, 1997).

Virtual worlds will not lead to the "collapse" of geography, as observers such as Cory Ondrejka have argued. They may, however, lead to the collapse of distance. In most virtual worlds, people can teleport from one location to another; in *Second Life*, residents can fly as well as teleport. Traditional distance-related location factors may no longer pertain, except at the local level, as people no longer need to accommodate the friction of distance in a world of instant transport.

Place, on the other hand, still exists. Indeed, the central purpose of the virtual world is to construct a place in which participants can create a shared sense of presence (albeit in avatar form). Participants may be scattered across the world, but they can be within speaking distance of each other to join in a meeting, to engage in friendly chatter, or to have a night out on the town. Furthermore, as in the real world, places may be distinguishable by culture group, nationality, lifestyle choice, and personal interests—note, for example, the Amsterdam, Copenhagen, and Zurich locations. Other

places provide nonthreatening and anonymous spaces for groups that may have relatively few such options in the real world; this advantage has been noted by some members of the gay community. Finally, a virtual world offers nearly unlimited opportunities for geographers (and others) who want to provide 3D physical and social modeling of places.

VIRTUAL GEOGRAPHIES

Virtual geographies are a broad area of research within geography and geographic information science that seeks to understand how new digital technologies and modes of communication are creating new notions of space and place. Among those areas of interest are the creation and exploration of virtual environments, including virtual worlds, cyberspace, and cybergeographies, and notions of other invisible social spaces. As the Internet, the World Wide Web, and other communication technologies continue to expand their roles in everyday lives, the study of the virtual geographies of evolving digital society will become an even more important component of the discipline. Understanding the virtual geographies they create, whether they be virtual worlds we inhabit through our avatars, the rapidly changing invisible landscape of cyberspace, or the virtual spaces of social interaction, will become an increasingly important aspect of understanding geography itself.

Perhaps the most recognizable of virtual geographies are digital reconstructions of landscapes, whether real or imagined. Recent advances in affordable graphics technologies are now moving far beyond the static two-dimensional paper map and providing researchers with the tools to not only generate nearly photo-realistic three-dimensional virtual landscape environments but also incorporate realistic light and textures as well as replicate physical systems such as cloud and water movement, fog, and weather. Computer and video games now routinely feature extensive virtual worlds with recognizable geography and real-world behaviors, and the ability to achieve a high level of realism is a key element in the commercial success of such games.

Creating a sense of immersion through the generation of such lifelike virtual landscape features, combined with camera perspectives and navigation that mimic human perceptions of movement through space, is a key element in generating the sense of immersion and interaction that allows users to feel as if they are experiencing a virtual landscape. To further enhance the sense of immersion within the virtual world, many researchers are turning their attention to developing tools

and mechanisms for conveying other sensory aspects that imbue a location with a sense of place, such as sound and even smell.

Until recently, much of the work in the development of virtual landscape reconstructions was focused on individual virtual-world projects, but the rapid adoption of Internet technology has spurred the development of online virtual worlds such as Linden Lab's *Second Life* (<http://secondlife.com>). These new collaborative virtual worlds are beginning to demonstrate the power of such environments for the generation and shared exploration of digitally re-created spaces and places. These virtual worlds, based on either real-world or fantasy landscapes, provide users a familiar way in which to interact with a digital landscape, as they move and interact with virtual elements through an avatar, a virtual self. In addition, activities in many virtual worlds such as *Second Life* are centered on building spaces and places within the virtual platform, creating new virtual geographies that do not necessarily have direct analogs within the real physical world. However, the geographic principles that seek to explain how humans shape and interact with space and place are clearly visible within these virtual geographies.

In addition to the virtual geographies represented within virtual worlds, the development of networks to connect computers has also led to the development of virtual geographies that represent the spatial structures of those networks. Often referred to as *cyberspace*, a term coined by William Gibson to describe the invisible spaces that represent the connectivity among computers, the virtual spaces of the Internet and the World Wide Web have their own spatial relationships and structures. Several geographers interested in attempting to identify and understand how these spaces are formed and evolve began a research initiative in 1996 with an emphasis on mapping and measuring the spatial aspects of cyberspaces, which was dubbed *cybergeography*. These efforts have focused on attempting to graphically illustrate the invisible structure of the Internet and the World Wide Web, from maps of Internet traffic to data flows and even the paths navigated through individual Web sites. The rapid rise in popularity of Web-mapping applications such as Google Maps, which allow users to map their

own data onto free base geographic data layers, has also spurred the development of new spatially oriented virtual communities and social networking sites that are creating their own virtual geographies. As these technologies migrate to mobile platforms, they are changing the ways in which people inhabit physical and virtual spaces and redefining how they form a sense of place.

The increasing focus on the exploration of virtual spaces created by these new technologies has also broadened to include other notions of invisible spaces, such as the virtual geographies of human social behavior and how they are being shaped by new communication technologies. For example, recent work has looked at wide-ranging topics such as the virtual geographies of Internet commerce (e-commerce) and virtual geographies of the body and self.

VIRTUAL GLOBES

A virtual globe is a computer software that allows interaction with a three-dimensional (3D) representation of Earth or another world. Virtual globes belong to a group of applications collectively termed *geobrowsers*, which include modern Web-based dynamic maps. Geobrowsers are a key component in the development of “neogeography” as they provide a medium through which

users can organize, search, and visualize information according to geospatial parameters. Virtual-globe technology has been available for over a decade but entered mainstream consciousness only with the release of Google Earth in 2005. The subsequent popularity of this software has inspired a rapid evolution in the features and capabilities of many virtual globes. This entry provides an overview of their history and popularization, describes the different types of virtual globes, and discusses their evolving capacity to create and display geospatial data.

History and Popularization

The creation of virtual globes is the result of 3D software, virtual reality and hypermedia, and remote-sensing technology developments that have been ongoing since the 1970s. It was Neal Stephenson’s 1992 novel, *Snow Crash*, that popularized the concept of a computerized globe showing dynamic imagery and inspired the initial real-life development of such programs. In *Snow Crash*, the primary protagonist accesses a software program called “Earth” that was created by the Central Intelligence Corporation as a user interface to their geospatial information, including weather data and real-time satellite surveillance. This “live” virtual globe presents greater capabilities than current real-world programs; however, virtual-globe technologies are developing increasing abilities to display dynamic data.

Inspired by *Snow Crash*, Mark Pesce, a cocreator of Virtual Reality Modeling Language (VRML), developed WebEarth, an open-source VRML application that builds a model of the Earth from composite satellite images. The first commercially available virtual globe to display dynamically updated earth data (clouds) was EarthBrowser. It was originally released in 1998 as a Macintosh shareware product called *Planet Earth* and continues to be developed by its creator, Matt Giger, for both Macintosh and Windows platforms.

An explosion of virtual-globe technologies occurred in 2001 with the development of Keyhole’s Earth Viewer (acquired by Google in 2004 and released in 2005 as Google Earth), Skyline-Globe, SINTEF (Norwegian: Stiftelsen for industriell og teknisk forskning [The Foundation for

Scientific and Industrial Research]) (Norkart since 2006) virtual globe, and Geofusion's GeoPlayer. However, it was the release of the open-source project NASA World Wind (2004), followed by Google Earth (2005), that brought virtual globes to the attention of a wider audience. In 2005, the use of these tools to aid rescue and relief efforts related to Hurricane Katrina received media coverage demonstrating the abilities offered by virtual globes, and their day-to-day use entered the public consciousness. By June 2008, downloads of Google Earth, the most widely used virtual globe, had topped 400 million.

Both NASA World Wind and Google Earth were developed as stand-alone applications. In contrast, Microsoft leveraged existing server and mapping technologies to create its Virtual Earth platform. It powers Live Search Maps inside an Internet browser. Released in 2005 as a 2D mapping product, it evolved into a globe application when 3D viewing capability was added in 2006. Unique to Virtual Earth is the inclusion of high-resolution aerial photography captured from a bird's-eye perspective view.

Similar to Microsoft, ESRI (Environmental Systems Research Institute) developed globe technologies that complemented existing products. In 2003, they released ArcGlobe, a 3D analyst extension to ArcGIS 9. This was followed in 2006 by ESRI's stand-alone globe, ArcGIS Explorer. Similar to most virtual globes, this is a free-to-download product, but its capabilities are greatly expanded when used in conjunction with ArcGIS server.

Currently, Google and Microsoft represent the leaders in virtual-globe technology with hundreds of millions of users, with World Wind and ESRI garnering tens of millions of users. Developments in mobile and multitouch technologies are leading to the next developments in virtual globes. New applications (e.g., Earthscape, developed using the iPhone Software Developer Kit), are making virtual globes accessible anywhere cell phone coverage can be found.

Types of Virtual Globes

There are two primary types of virtual globes. One attempts to create a realistic mirror of the real world, while the other type is based on graphical

representations of global information data sets. "Real-world" globes, such as NASA World Wind, Google Earth, ESRI ArcGIS Explorer Microsoft Virtual Earth, and SkylineGlobe, create a representation of Earth by tiling high-resolution satellite imagery and aerial photography over a digital elevation model of the underlying terrain. Both Google and Microsoft invest considerable time and effort into acquiring, processing, and serving high-resolution imagery. World Wind, an open-source community project, uses mostly public domain data sets such as Landsat 7 imagery and Shuttle Radar Topographic Mapping (SRTM) project terrain. Other real globes built on open-source virtual globes, for example, Ping's 3Map (based on WebEarth), Dapple, and Punt (based on World Wind), also leverage the same data sources. Similarly, small development projects (e.g., Earth-Browser, Norkart Virtual Globe, and Poly9 Free-Earth) rely on public data sets and have a limited coverage of high-resolution imagery.

The second type of virtual globe provides a global representation of data sets with limited or no land cover imagery. These "specialized" globes are representations of social, economic, infrastructure, or environmental data (e.g., Global-i). A common application for these globes is weather visualization (e.g., Software MacKiev's 3-D Weather Globe & Atlas). The key requirement for these globes is the ability to update data dynamically—a feature that is also used within integrated data layers in "real-world" globes, for example, the Google Earth weather layer.

Geospatial Content

The ability of virtual globes to display dynamic content makes them more than just a Web-based map or simple satellite image representation of the world. Most virtual globes provide integrated "layers" of content both static (e.g., political borders) and dynamic (e.g., clouds) in nature. They also allow users to add their own geospatial data. The standard that emerged to create content for virtual globes is an object-oriented extensible markup language, Keyhole Markup Language (KML). Originally developed by Keyhole and then Google, after their purchase of Keyhole, Inc., in 2007, KML was submitted to the Open Geospatial Consortium to become an

open standard. It was officially accepted as an international standard on April 14, 2008. Through KML, developers, scientists, educators, and anyone with georeferenced information have the ability to create informative visualizations and display them within a range of virtual globes and other geobrowsers.

VISION AND GEOGRAPHY

Vision has been a topic of much interest not only for geographers but also for philosophers, painters, photographers, filmmakers, art historians, and cultural theorists. Since vision is studied and understood differently by a variety of people, it should not be expected that its theoretical and material impacts could be experienced in a similar vein. Vision has long been a concern for ontology (the study of existence), epistemology (the theory of knowledge and its production), and methodology.

Modern Western society has held vision as the paramount sense called on to produce knowledge, suggesting that seeing means knowing. Geography has a long-standing relationship with visual culture and has often been called a *visual discipline*. The link between vision and order, classification, and description has heavily influenced geographic thought. Throughout the late 19th and part of the 20th centuries, geographers were expected to describe, understand, and represent the world through maps or words completely and objectively. Geographers relied heavily on their senses, predominantly vision, to draw empirical or experience-based conclusions. Today, vision continues to dominate contemporary geographic research. However, in the past few decades, much work has been done by geographers and others concerned with the visual to recognize that vision cannot be taken as given. Ways of seeing, imagining, and representing what is seen are now understood to be the effect of specific social and technological circumstances.

Geographers approach the spatiality of vision in exciting and innovative ways. Contemporary human geographers have explored social practices that construct visibility, examined images that give shape to geographical imaginations, and engaged with various technologies of vision that design ways of seeing. They examine and produce meaning through map making and geographic information systems imagery by reading landscapes as visual texts and by investigating representations of space in a variety of media, such as painting, photography, and film. In the past 30 years, geographers have become increasingly concerned with representations of space within the visual field. Denis Cosgrove greatly influenced the way geography approaches the visual. He engaged with cultural landscapes not as passive objects but as sites where power relations, gender roles, national identity, political ideologies, and other social processes are actively produced. His scholarship pursued a new line of inquiry and methodology within human geography. Stephen Daniels and Denis Cosgrove, among others, began to apply iconography (a critical reading of imagery to explore cultural values) to interpret images as socially, historically, and spatially contingent texts. Images are now understood not simply as mimetic evidence of objective, stable, and complete realities

but as powerful tools that actively construct the geographic imagination.

Technology plays a critical role in producing new ways of seeing. Technological advances in image capture, such as photography and film, engineer space and reality in meaningful ways. For example, with the advancement of aerospace engineering, images of Earth were taken that captured our planet in its entirety, representing Earth as being within the control of humans and our technologies and thus playing a powerful role in furthering political imaginations and geocultural agendas.

To address questions related to the ontologically stable world images present, many geographers have drawn on poststructuralist thought. Poststructuralist theory advocates that what is understood as material reality is a pieced-together fiction that is fragmented, partial, and multiple. Theorists such as Michel Foucault and Jacques Lacan have been instrumental in conceptualizing vision, visibility, and the function of the gaze for the modern subject. Vision is understood as what the human eye is capable of seeing within the visible portion of the electromagnetic spectrum. Visibility is broadly understood as socially produced and perspectival. Visibility is a process that is historically, spatially, and technologically contingent. The concept of the gaze is integrally connected to vision and visibility. Michel Foucault's understanding of the relationship between the gaze and subjectivity has been highly influential in geography and the social sciences more broadly. Foucault argues that the modern subject internalizes the panoptic gaze and is under perpetual surveillance both by himself or herself and by others. This understanding of the gaze renders the modern subject as fully visible, trackable, and governable. The psychoanalytic theorist Jacques Lacan's notion of the gaze is distinct from the act of looking—the eye and the gaze are split from one another. The gaze itself is the object of looking and does not belong to the subject but rather to the object, such as a painting or a film. Lacan's theorizations of the gaze were taken up by psychoanalytic film criticism in the 1970s. The so-called Lacanian film theory is the site of much theoretical confusion and is being rearticulated by many scholars advancing a more rigorous understanding of the Lacanian gaze.

Geographers are engaged with the visual in a variety of contexts. Gillian Rose dedicated much attention to the relationship between geography and the visual. She examined how geographical knowledge within academia is constructed, packaged, and presented through visual tools such as PowerPoint slides, questioning a neat presentation of images on a slide that portrays knowledge as being spatially captured, stable, and whole. Marcus Doel and David Clarke have written on the ways by which the visual is constructed in film by film and in particular how montage, the assemblage of parts, is central to the relationship of human geographers to the visual. Increased research has been initiated on how to produce new ways of seeing through geographic information systems (GIS) and what representational practices are embedded in this powerful visual technology. Chris Lukinbeal is advancing research on analyzing the visual products generated by GIS. He explores how these technologies are put to work in the academy and in broader social contexts. Also, through critical map reading, geographers have produced insightful scholarship on how maps play a role in the construction of tourist spaces and consumer identities. Many geographers are moving toward a geography that does not rely so heavily on the visual and accesses other senses for knowledge production. However, because of geography's deep roots within the visual field, it is still robust terrain for geographical inquiry.

VOLCANIC ERUPTIONS AS RISK AND HAZARD

Volcanoes are a principal agent of degassing of the interior of the Earth and other planets. They are thought to be the main source of the Earth's atmosphere and hydrosphere, and thus they are a vital part of the sustainable Earth system. Volcanic activity has provided the air we breathe and the water that makes up most of our body mass. Volcanism also provides vital enrichment to the Earth's soils, particularly in tropical areas. In spite of the long-term benefits, the effects of eruptions can be seriously negative in the short run, so volcanoes can be considered a type of natural hazard that threatens life and property.

Among natural hazards, volcanoes have caused far fewer deaths and damage to property historically than have floods, coastal hazards, and earthquakes and so are considered hazards of local or minor rank by some people. The historic record may be misleading because it is brief compared with geologic time and because large eruptions occur too rarely to have been accurately assessed and understood. There are at least 1,500 volcanoes that are considered active in the world, and about 400 have erupted in the past century. Eruptions span at least eight orders of magnitude, ranging from erupted magma volumes of less than 10,000 m³ (cubic meters) to more than 1,000 km³ (cubic kilometers). But most eruptions are quite small in scale, and their hazards are generally quite localized to areas near the volcano. Larger eruptions are known to have global impact, but because of their statistical rarity, the

scientific understanding of these events is very limited. Understanding of the largest eruptions (super-eruptions) is the most limited, but these possibly include worldwide loss of multiple growing seasons and huge global loss of life (volcanic winter).

The assessment of volcanic hazards begins with geologic maps, which record the distribution of past volcanic deposits that reflect past activity and the locations where hazardous events occurred, leading to hazard maps that cover the volcano environs, especially in areas downslope from active vents. Volcanic deposits are dated to assess the frequency and probability of hazards, and vulnerability is assessed through geographic information system population density maps and social science surveys. The topography of areas near volcanoes provides an important key to hazard zonations, because many types of volcanic hazards are governed by gravity and the damaging volcanic agents (lava flows, pyroclastic flows, mudflows, avalanches, debris flows) descend from high to low elevation following valleys. A useful tool in hazard work has been the development of numerical models of hazards, which can be applied to the individual topography to derive "objective" hazard maps. Completed hazard maps exist for only a small fraction of Earth's active volcanoes. To accompany hazard maps, hazard reports are written in plain language for the public to explain the nature of hazards that occur during eruptions. These reports are used in local communities and especially schools. Where risk is high, additional measures for public education and outreach are undertaken, and zoning measures may be implemented.

Atmospheric hazards that result from eruptions are of special interest, because they typically extend farther from the volcano and may thus affect a broader area. Explosive eruptions create finely divided magma that transfers its heat rapidly to the air and rises to stratospheric height. Since many particles are so fine that they do not fall, they can be carried hundreds to thousands of kilometers before fallout. Ice nucleates on this fine ash and helps it grow and fall out. Stratospheric ash is a severe aircraft hazard, while fine ash fallout can occur on a continental scale in super-eruptions and is a deadly hazard to lungs. Ash fallout masses and particle sizes decrease

A blanket of ash covers Subic Bay Naval Base in the Philippines in the aftermath of Mount Pinatubo's eruption, June 1991. The volcano, which erupted for the first time in more than 600 years, forced the U.S. military to coordinate Operation Fiery Vigil evacuation efforts to remove more than 20,000 evacuees from the area.

Source: Sgt. Paul Bishop.

with distance for the first 100 kilometers or more, but distal fallout is governed by meteorological processes and may result in heavy fallout far from the volcano. Sulfur dioxide is a second hazardous material contributed by eruptions to the stratosphere. It reacts with the atmosphere and forms sulfuric acid, which exists as a liquid aerosol particle that stays in the stratosphere much longer (a few years) than ash (a few days) and can create stratospheric warming and surface cooling.

Although monitoring of volcanoes is likely to lead to successful forecasting of most eruptions, many volcanoes remain completely unmonitored because of insufficient funds. Many more have only very limited monitoring. New holistic assessments of volcanic threat that measure population distributions and hazards beyond the immediate vicinity of the volcano (especially those to aircraft) are now being employed to guide decisions about which volcanoes should have priority for monitoring in the public interest. Remote satellites are used to measure thermal anomalies,

surface deformation, gas emission rates, and vegetation changes at volcanoes around the world to provide direct field information at unmonitored volcanoes. A worldwide alert system exists to integrate ground monitoring data and satellite observations in order to provide volcanic cloud hazard warnings to aircraft, which are especially vulnerable at night.

Many volcanoes are far from human population centers, but there are especially important volcanic hazard sites where active volcanoes occur near large cities (e.g., San Salvador, El Salvador; Guatemala City, Guatemala; Mexico City, Mexico; Quito, Ecuador; Naples, Italy; Auckland, New Zealand; San José, Costa Rica; Shimabara, Japan). The realization of the vulnerability of these cities to volcanic hazards has led to multidisciplinary hazard studies aimed at mitigation, which employ monitoring, public communication, and outreach.

VOLCANOES

The spatial and temporal distribution of volcanism on Earth's surface is associated with geodynamics. Volcanic morphology is related to physical properties and chemical composition of the magma governed by the tectonic setting as well as exogenous processes over geological time. Eruptive activity comprises phenomena that are potentially dangerous to humans and infrastructure. The negative effects of those phenomena, however, can be minimized with hazard evaluation studies and volcanic monitoring. In contrast, eruptive activity has generated some of the most fertile soils of our planet, geothermal energy is produced from the internal heat of volcanic systems, volcanic materials have constructive and industrial uses, and volcanic landscapes are tourist sites.

Volcanism

Volcanism is directly related to the internal structure of Earth and interaction among tectonic plates. Volcanism occurs in divergent and convergent boundaries. Divergent boundaries occur within ocean basins and continents marked by midocean ridges and rift valleys, such as the Icelandic volcanism and Great Rift Valley of East Africa, respectively. Convergent boundaries are complex according to the kind of plate's interaction: oceanic plate/oceanic plate, oceanic plate/continental plate, or continental plate/continental plate. Intraplate volcanism occurs less frequently, either undersea as in the Hawaiian Islands or in continents such as the Yellowstone Volcanic Field. Geodynamic settings determine the physical and chemical characteristics of the magmas.

Magma is molten rock of silicate composition. Magma is generated by the partial melting at the asthenosphere or within the lithosphere. There rocks are under high pressure and temperature, and just slight changes due to increase in temperature, decompression, or addition of fluid phases can cause rocks to melt to generate magma. The lower density of the magma compared with the surrounding rock favors the ascent. During the ascent, processes such as fractional crystallization, magma mixing, assimilation, and contamination modify the original chemical magma composition and determine their temperature, viscosity, and gas contents and consequently the type of eruption.

The classification of igneous rocks is based on texture and chemical and mineralogical composition. Texture reflects the conditions of cooling. Coarse-grained textures with large crystals result when magma cools slowly beneath the surface. Fine-grained textures occur when lava cools rapidly at the surface. Basalt, andesite, dacite, and rhyolite are the common extrusive igneous rocks. Gabbro, diorite, granodiorite, and granite are their intrusive equivalents. Petrologic studies elucidate the origin and evolution of magma that generates igneous rocks.

Types of Eruptions

Eruptions occur when the magma reaches the surface through a vent or crater. However, magma

also erupts through fissures on the flanks of a volcano or in flat areas. An initial classification of eruptions differentiates between effusive and explosive eruptions.

Effusive eruptions are characterized by emissions of lava. Eruptions of low-viscosity and high-temperature lavas produce *pahoehoe* morphological features. In contrast, *aa* lavas present a fragmented and rough morphology due to a relatively higher viscosity. With the increase in viscosity of lavas and decrease of temperature, domes may form. The accumulation of lavas over geological time generated shields, composite, and stratovolcanoes. The eruptions of Hawaiian volcanoes are typically effusive.

Explosive eruptions are produced by the sudden separation of volatiles from magma, fragmenting it and the surrounding rocks inside volcanic edifices. Volcanic explosions eject fragmented material known as *tephra* into the atmosphere by eruptive columns or produce pyroclastic flows sweeping the volcanoes' flanks. Tephra includes various sizes of particles: block (>64 mm [millimeters]), lapilli (2–64 mm), and ash (<2 mm). Due to temperature contrasts with the atmosphere, it rises until it loses buoyancy and then travels under the influence of the wind and falls, mantling the landscape with a thickness from millimeters to meters. These deposits are called *fall deposits*. Based on the analysis of distribution, thickness, and chronostratigraphic studies of fall deposits, volcanologists infer the magnitude and development of an eruption. When an eruptive column collapses due to its high density, dense clouds of tephra flow down over the volcanoes slopes, forming pyroclastic flows. A pyroclastic flow consists of a hot mixture of fine and coarse fragments of rock, pumice, and gas, and its flow is controlled by the topography, moving fast along canyons or ravines until it stops and the material is deposited. According to the components, ash flows, pumice or scoria flows, and block and ash flows can be distinguished.

In some volcanoes, magma intrusion may produce partial collapse and a blast. Magma intrusions increase the pressure on the volcano's flanks, provoking the partial collapse of the edifice and a sudden release of the lithostatic pressure over the magma body, producing a lateral

blast. The sector collapse generates a debris avalanche whose distribution is not governed by the topography, covering large areas and traveling considerable distances. Its morphological features are characterized by conic mounds called *hummocks*.

The Volcanic Explosivity Index (VEI) describes the magnitude of explosive eruptions. VEI ranges from 0 to 8; each increase represents a factor of 10 in the volume of erupted material. Determination of an eruption's VEI depends on the volume of erupted material, height of the column, and duration. The AD 79 eruption of Vesuvius (Italy), which destroyed Pompeii and Herculaneum, had a VEI of 5.

Volcanic Morphology

Volcanoes are endogenous features. Their shape and dimensions depend on geodynamic settings, magma production, and emission rates. According to morphology, they can be scoria (cinder) cones, domes, shield volcanoes, composite volcanoes, calderas, maar, tuff rings, and tuff cones.

Cinder cones are made of tephra falls that accumulate around the vent. They may grow on the flanks of shield volcanoes, composite volcanoes, and calderas. Cinder cones are born to constitute volcanic fields with eruptions lasting from days to years. An example is the birth of Parícutín volcano in Western Mexico in 1943; its eruption lasted 9 years, with social, economic, and ecological effects on the region.

The morphology of lava domes varies from dome shapes to pinnacles or spines. The domes may grow on the slopes or within the crater of composite volcanoes. As a dome grows, its surface cools, and partial collapses of it can generate pyroclastic flows. Domes can seal the conduit system, provoking the pressurization of the volcanic system and triggering explosive eruptions. The eruption of Mt. Pelée (Martinica Island) in 1902 resulted from dome growth.

Shield volcanoes owe their name to their similarity in shape with the old European warrior shields. They are built by the piling of successive lava flows erupted from a central vent or fissures on volcano's flanks and are slightly convex, with gentle slopes and sometimes with a caldera or cinder cones on top. Mauna Loa (Hawaii) is

The May 18, 1980, eruption of Mt. St. Helens, an active volcano in Washington State, had a VEI of 5.

Source: National Oceanic and Atmospheric Association News Photo.

considered the largest and one of the most active volcanoes of Earth; its height from the ocean floor is approximately 10 km (kilometers). According to their basal diameter and height, shield volcanoes are classified as Hawaiian (Mauna Loa, Mauna Kea), Galapagos (Alcedo and Cerro Azul), Icelandic (Skjaldebreidur and Skalarfell), or Mexican (Cerro Grande and Santa Clara).

Lavas and pyroclastic material make up composite or stratovolcanoes during their complex and large evolution. Symmetrical cones, steep slopes, and a crater at the summit are their morphological features. The magma rises from magmatic reservoirs through conduit systems to reach Earth's surface. Eruptions at composite volcanoes generate lava domes, eruptive columns, and pyroclastic flows or undergo partial collapses. Mt. Fuji (Japan), Mt. Rainier (United States),

Popocatepetl (Mexico), and Arenal (Costa Rica) are examples of active composite volcanoes. High-altitude or high-latitude volcanoes host glaciers at their summits. Interaction between volcanic activity and the presence of ice bodies may produce the debris flows or lahars that sweep the volcanoes slopes. Also, rainfall may remobilize loose tephra to form lahars.

A caldera is a negative morphological element with a circular to elongated concave shape of several kilometers. The origin of calderas is associated with major eruptions. Magma is erupted through vents and as the magmatic chamber is emptied, subsidence occurs and a depression is formed and lavas and pyroclastic flows are distributed over a considerable area. Voluminous pyroclastic flow deposits with a variable degree of consolidation are generated. Crater Lake (United States) with a diameter of 9 km was produced by

Mt. Mazama's eruption in 6800 BC. Other calderas are Taupo (New Zealand), Santorini (Greece), and La Primavera (Mexico).

When magma encounters water bodies such as the sea, lakes, rivers, or aquifers during its ascent to the surface, explosive eruptions are generated. The temperature differences between magma and water suddenly produce steam. The resulting increase in volume fragments the magma and the surrounding rocks. Ejected material deposited in the proximity of the vent builds up tuff cones. A greater dispersion of ejected material forms tuff rings. A maar is a low-relief form, like a crater produced when explosions fragment the surrounding rock, leaving no deposits around. Maars are often filled with water and form small lakes.

Volcanic Hazards

Volcanic phenomena such as lava flows, tephra falls, pyroclastic flows, debris avalanches, lahars, gas emissions, earthquakes, and tsunamis are potentially dangerous to humans and the environment. Hazard evaluation and monitoring of active volcanoes or volcanic fields can reduce volcanic risk. Hazard evaluation includes the study of historical eruptions, characterization of eruptive activity through time, and analysis of volcanic deposits using stratigraphic, geochemical, geochronological, and geophysical criteria, allowing determination, with an acceptable degree of uncertainty, of the type, extent, and spatial distribution of volcanic products.

Monitoring networks for follow-up of volcanic seismicity, deformation, gas emission, and geochemical and hydrological changes, among others, provide valuable data for the forecast of eruptive processes and associated hazards over the course of an eruption.

Hazard evaluations and monitoring data are of great importance to decision makers for land use planning and protection of people who live under the threat of volcanic hazards.

Volcanic Areas as a Source of Natural Resources

Volcanic soils cover extensive areas around the Pacific, East African Rift Valley, the Canary

Islands, and Azores and are considered among the world's most fertile soils. Most areas covered by volcanic soils are at the same time exposed to volcanic hazards; however, hazards evaluation studies can reduce the potential risks to population and infrastructure. Ore deposits are associated with magmatic processes. Crushed lava, pumice, and scoria are the source for construction and industrial raw materials.

At some places, close-to-the-surface stagnant magma bodies heat groundwater, generating geothermal systems, which are used as hot mineral springs for bathing, cooking, or heating. Geothermal energy provides heat for 90% of the housing in Reykjavik (Iceland), and geothermal power plants generate electricity. The United States is the world's largest producer of electricity from geothermal energy.

Volcanoes are among the most scenic landscapes around the world; these include Thínvellir (Iceland), Teide Volcano (Canary Islands), Mt. Fuji, Unzen Volcano (Japan), Arenal Volcano (Costa Rica), Pacaya Volcano (Guatemala), Vesuvius Volcano and Pompeii (Italy), Villarica Volcano (Chile), Hawaii (United States), and so on. These tourist sites attract millions of visitors each year. The United Nations Educational, Scientific and Cultural Organization considers some volcanic areas as "geoheritage" sites. In addition, other geological or geomorphologic elements of nature are often worthy of being preserved, and they form part of geoparks, which are sites with geological, archaeological, ecological, and cultural significance. Geotourism, education, and sustainable development are the main components of the geoparks. Kawaninka Geopark in southwest Australia comprises volcanic cave systems, offshore volcanic island, dormant volcanoes, craters, lakes, and wetlands. Magma Geopark in southwest Norway consists of intrusive igneous rocks that crystallized 930 million years ago. Cultural history related to mineral exploitation and the rounded outcrops characterizes the landscape.

VORONOI DIAGRAMS

The Voronoi diagram (also called a *Dirichlet tessellation* or a set of *Thiessen polygons*) is a partition of a metric space such that we associate all locations in that space with the closest object in that space, based on the specified metric. Thus, each object is the generator of a cell or tile, and the set of tiles covers the space or map.

In the simplest case, we are given a set of points S in the Euclidean plane, which are the Voronoi generators. Each generator, s , has a Voronoi cell, $V(s)$, consisting of all points closer to s than to any other generator. The cell boundaries of the Voronoi diagram are all the points in the plane that are equidistant to two generators, and the Voronoi nodes are the points equidistant to three (or more) generators. Voronoi cells can be defined for metrics other than Euclidean, such as the Manhattan distance, and for other surfaces than the plane, such as the sphere. Voronoi cells can also be defined by measuring distances to objects that are not points. The dual graph of the Voronoi

Figure 1 The Voronoi diagram of a set of points, together with the dual Delaunay triangulation

Source: Author.

diagram of S corresponds to the Delaunay triangulation (DT) of S (Figure 1). Here, all Voronoi cells have generators that form the vertices of the DT, all Voronoi edges have perpendicular Delaunay edges, and all Voronoi vertices are the centers of the circumcircles of the DT.

The idea of the Voronoi diagram is relevant in many spatial sciences, giving descriptions of proximity, adjacency, clustering, territoriality, and others. The DT is widely used as a stable and well-defined triangulation for terrain modeling. Informal use of Voronoi diagrams can be traced back to Descartes in 1644. The Voronoi diagram was used in 1854 by the British physician John Snow to show that the majority of people who died during the cholera epidemic in the Soho district of London lived closer to the contaminated pump at Broad Street than to any other source of water.

Properties

Given a set of service locations (e.g., post offices), the Voronoi diagram identifies the closest service to any particular location. The location furthest

Figure 2 The crust (boundary) and skeleton (medial axis) of points along the boundary of a closed shape are formed from subsets of the Voronoi diagram and the Delaunay triangulation.

Figure 3 Approximate catchment analysis. Points on the rivers are digitized and the Voronoi diagram/Delaunay triangulation constructed. Voronoi vertex circle radii are interpreted as heights, giving a simple terrain model. The local runoff area of the river points is given by their Voro.

Source: Author.

from any point in S is one of the vertices of the Voronoi diagram of S . This has the largest possible empty circle within the map. This is equivalent to the triangle in the DT of S with the largest circumcircle. Every triangle in the DT has an empty circumcircle. Equivalently, every edge in a DT has an empty circle touching the two ends. Given a set of n points in S , the closest pair of points will be on an edge of the DT of S . Similarly, the nearest neighbor to each of a set of points will be defined by an edge of the DT of S . The Euclidean minimum spanning tree of a set of points S is a graph without any cycles that connects all points in S with a minimum total edge length. It is a subset of the edges of the DT of S . The DT is a planar graph. By Euler's formula, it has at most $3n - 6$ edges and at most $2n - 5$ triangles. The convex hull of S is a subset of the edges of the DT. The DT maximizes the minimum angle of each triangle by comparing it with its neighbors. This approach gives the fattest triangles possible for the set S (Figure 2).

Voronoi diagram construction is "local": Inserting a generator adds a new cell that was "stolen" from its neighbors. Thus, the Voronoi diagram and the resulting DT may be updated locally. If the set of points S are on the boundary of a closed shape, then the medial axis transform (MAT), or skeleton, is a subset of the Voronoi edges (the Voronoi vertices have empty circumcircles). In three dimensions, many of the properties described above for two dimensions still apply.

Applications

Apart from geography, many disciplines use Voronoi diagrams, including: cosmology (e.g., galaxy clustering); biology, ecology, forestry, and zoology (e.g., plant and animal competition, tree crown areas); geology (e.g., ore reserves and simple mapping based on a Voronoi cell around each drill hole or outcrop, surface and

volume interpolation, fluid flow); meteorology (e.g., rain-fall based on a Voronoi cell around each rain gauge); robotics (e.g., path planning from the medial axis); and pattern recognition (e.g., crust/boundary and skeleton/MAT for points representing an object boundary).

In geography, the Voronoi diagram is used for cluster analysis, point pattern analysis, location optimization, surface and volume interpolation, surface modeling from contour maps, growth models, adjacency analysis, buffer zone calculation, collision detection in dynamic systems, fluid flow simulation rapid digitizing of polygon maps, reconstruction of scanned maps, merging of field and object data in a geographic information system, runoff modeling, watershed estimation, catchment analysis, and region detection in remote sensing, to name a few (Figures 3 and 4).

The primary value of the Voronoi diagram is that it provides a mathematically defined and consistent allocation of space to the nearest generator. This property leads directly to the idea that the Voronoi boundaries are equidistant between generators and hence may be used for path planning and medial axis generation. Similarly, as all spatial locations are assigned, the resulting tessellation provides a functional definition of adjacency between discrete objects, based on geometry alone, which provides useful techniques for cluster analysis, interpolation based on the immediate neighbors to the unknown point, and collision detection for moving vehicles or interactive map construction. The dual DT, based on the Voronoi diagram, is valuable both because it minimizes splinter triangles and because individual updates only change local portions of the map.

VULNERABILITY, RISKS, AND HAZARDS

Study of hazards involves the concepts of vulnerability, risks, and hazards, with hazards research evolving to include considerations of social vulnerability and resilience. Although public use of the words *vulnerability*, *risk*, *hazard*, and *threat* has sometimes been interchangeable, each word has its own distinct definition within the field of hazards geography.

Hazards

Hazards represent threats of potential damage or destruction to individuals and society. The actual hazard event, such as a flood, earthquake, wildfire, blizzard, or nuclear reactor accident, may result in a disaster if the incident results in substantial human disruption, whether measured by property damage, injury, or loss of life. An event must have the potential to be sufficiently disruptive of human activities to be considered a hazard, thus the physical magnitude of the event that is considered a hazard varies geographically and temporally. For example, several centimeters of winter snow would be considered routine in the northern Midwest, while it would pose a significant hazard in Southern Florida. Likewise, routine moderate precipitation is not considered a hazard but a valuable resource. However, too little or too much rain results in drought and flood hazards, respectively. Indeed, hazards are sometimes termed *negative resources*.

Geographic study of natural hazards grew out of the pioneering work of Gilbert White, nearly three quarters of a century ago, dealing with river flooding. Because flood losses were increasing even though substantial investments had been made in the construction of dams and levees, White saw the need to fully explore how human activity was related to flooding. To appropriately understand flood hazards, the complex interrelationships between the natural environmental systems that led to flooding and the web of human activity that resulted in lives and property being placed at risk needed to be thoroughly understood.

Natural and Technological Hazards

Building on these studies of flood hazards, the hazards field expanded to include not only a wide variety of geological, hydrological, and meteorological events but also many technological hazards, including those related to industrial and transportation accidents, releases of toxic chemicals and radiation, and pollution. At the same time, the study of hazards spread from American or European settings to less industrialized non-Western societies—although such studies remain in the minority. Hazards related to global warming are increasingly being considered, and studies have considered the consequences of such warming on drought, wildfire, and hurricane hazards, among other hazard threats. Furthermore, growing world populations have led to both overgrazing and deforestation, both events that may increase the likelihood of flood, drought, and landslide hazards. Thus, hazards may have either natural or human causes.

Recent research has included *Natech* hazards, those in which natural hazard events trigger technological disasters. Natech hazards include events such as flooding or seismic activity that spills toxic chemicals. The definition has expanded to include disruption of critical infrastructure, such as water supply lines, electrical transmission systems, or transportation networks, resulting from natural hazards.

Geographers have also studied the risk and distribution of various diseases from a hazards perspective, yet diseases and pollution have often been studied from other perspectives. Furthermore, geographic study and teaching about hazards often excludes disease and pollution hazards. While Ken Hewitt has proposed the geographic study of hazards of war, and others have studied terrorism hazards, these topics are ignored by the majority of hazards geographers. Nevertheless, urban violence, poverty, and street crime can all be studied from a hazards perspective.

Geographic study has tended to concentrate on the hazard itself, or the spatial patterns of disaster, while societal response and disruptions resulting from disasters are typically studied by sociologists. In studying hazards, geographers consider both the physical event and the human response or adjustment to it, as it is the complex

interactions of the physical and human systems that create and determine the intensity of the hazard. Changes in technology, human occupancy, and timing provide the context that can either accentuate or ameliorate hazards. While some geographers have emphasized hazards resulting from specific physical threats, others have focused on human responses, including perception, hazard mapping, land use planning, evacuation, and reconstruction, among other mitigation topics.

Human perceptions of hazards were viewed by Robert Kates as the first step in his Adjustment Process Control Model. Once the awareness of and concern about a hazard reached a critical threshold, an individual or group initiated a search for ways to reduce or mitigate that hazard threat. This search for adjustments was constrained not only by the searcher's knowledge of possibilities but also by economic, environmental, social, political, and technological factors. While the connections between hazard perception and adjustment behavior are often considered in hazard studies, the linkages are far from being direct. Many cultural and contextual issues influence and constrain perceptions of both hazards and potential adjustments, and much remains to be done to develop better models that explain human response to hazards.

NASA satellites capture remarkable images of the wildfires that raged in Southern California on October 22, 2007. This image shows the thick, billowing smoke coming off the numerous large fires and spreading over the Pacific Ocean. Fire activity is outlined in red. Dry, drought-stricken vegetation and Santa Ana winds, which can reach hurricane speeds, have contributed to the devastating effect of these blazes.

Risks

Risks have been loosely described as *environmental threats*, but risk can be viewed as a function of hazard and vulnerability. Risk is often defined as a measurement of the probability of experiencing an extreme event or an event of a particular magnitude. Although the public often misconstrues probability information, much geographic study of and societal response to floods has dealt with the concept of the 100-year flood, or a flood with a 1% probability of occurrence in any given year.

Flood Insurance Rate Maps display those areas of the United States with this flood risk, in which flood insurance and land use regulation are required. Other maps displaying the probabilities of experiencing a wide variety of hazards, including both river and coastal flooding, coastal storm surges, landslides, volcanic ash deposits and lahars, and seismic shaking and liquefaction, have been widely published. The consequences of this risk—the disaster potential—are related to both the physical hazard and the vulnerability of the population.

Vulnerability

Vulnerability to hazards varies depending on both the physical and the social setting of a community. Because vulnerability can be defined as the potential for and consequences of casualty or economic losses, it is not necessarily directly related to hazard risk or probability. For example, a playing field occupying a floodplain that is inundated every year or two is less likely to sustain property damage significantly disrupting human activities than a residential area located nearer the fringe of the floodplain that may be flooded every other decade. Thus, vulnerability is related to the physical probability that an area will be flooded and to the type of human usage of the site. While physical conditions determine the nature and frequency of the hazard event, social conditions control the land use and occupancy decisions regarding hazardous sites.

Social Vulnerability

Social vulnerability is strongly influenced by the income, racial or ethnic status, age, education, and political standing of a population. The poor are disproportionately more likely to occupy lands that are subject to frequent flooding or landslides and sites that are in close proximity to toxic waste dumps and industrial polluters. Wealthier individuals have the economic resources to avoid physically vulnerable sites and often have control of political institutions that may influence siting of such developments. Furthermore, the poor are most likely to occupy dwellings that provide minimal resistance to seismic shaking or offer little protection against high winds or floodwaters. Regardless of their residence, individuals who are elderly or disabled are more vulnerable to hazard occurrences and present challenges during both the evacuation and the disaster recovery periods. Polarization and spatial segregation of different socioeconomic groups result in their different vulnerabilities to hazards.

A “progression of vulnerability” has been identified by Ben Wisner and Piers Blaikie in their Disaster Pressure and Release Model to demonstrate how unsafe conditions interact with hazards to produce disasters. Root causes that are related to poverty and social marginalization lead to dynamic pressures that result in unsafe

conditions. These are manifested by populations living in dangerous locations, with inadequate incomes, and lacking public institutions that might mitigate or warn about the hazard threat. Economic vulnerability is enhanced when meager incomes are threatened by disaster-induced job losses. Certain types of employment are far more vulnerable to specific hazards than others. For example, peasant farmers are far more vulnerable to drought than urban workers.

Resilience

Resilience to hazard losses refers to individual and community attributes that enhance both loss avoidance and disaster recovery. Resilience can also be viewed as the ability to absorb or tolerate hazard consequences, both physically and socially. Resilient communities have greater abilities to recover from a disaster. Financial resources are key, inasmuch as wealthy groups can draw on existing resources to rebuild and restore homes, businesses, and damaged infrastructure. Likewise, wealthier individuals and groups are more likely to have incorporated hazard mitigation into the design and construction of their houses and businesses, thus reducing their vulnerability to hazard losses and increasing the likelihood that a hazard event will not result in an interruption of business activities. Resilient communities are less likely to suffer long-term losses of employment or public services, inasmuch as pre-event planning provides mechanisms to both avoid or minimize losses and to appropriately respond to changing conditions.

Hazards and Vulnerabilities of Megacities

The unique hazardousness of megacities has been described by geographers, most notably J. Kenneth Mitchell. Given their huge populations, which may be defined as exceeding 10 million residents, a disaster could potentially involve so many casualties and so much destruction of property and infrastructure that it would cause social and economic disruptions of entire nations. Megacities, which are disproportionately located in less developed countries, are also frequently located in low-lying coastal settings that are vulnerable to both coastal storms and sea level rise, both which could be exacerbated by global warming. Yet for many

hazard threats, such as tornadoes, landslides, and even some river flooding, only a portion of the megacity would be physically vulnerable to destruction from a particular event. In contrast, because of their much smaller geographic area, the entirety of a rural village or small town might suffer the consequences of such events. While the nature of the physical vulnerabilities of megacities and small communities varies for many threats, certain events, such as earthquakes or tropical cyclones can result in widespread destruction in megacities.

Megacities have greater resilience to hazards than smaller rural communities. Not only is the national wealth and political power typically concentrated within megacities, but also these cities have a disproportionate share of their nation's emergency response capabilities, including physicians and hospitals, firefighting equipment and personnel, and transportation links with the outside world. Nevertheless, the truly megadisaster does have the potential to overwhelm this response capacity, justifying the attention given to the hazard vulnerability of megacities.

Hazards and Vulnerability of Place

Geographic information science (GIScience) provides a powerful tool to analyze spatial variations in hazard vulnerability. While Ken Hewitt and Ian Burton promoted the concept of “hazardousness of a place” three decades ago by discussing all physical and technological hazards within a Canadian city, recent development of the “hazardousness of a specific place” concept by Susan Cutter involves spatial analysis tools that integrate physical vulnerability data and land use information with multiple measures of social and economic vulnerability. This work enables geographers and emergency planners not only to identify the specific locales within a community that have the greatest physical vulnerability to a particular hazard or group of hazards but also to input the character of the built environment (density and quality of construction, type of land use), the social characteristics of the population, and

the location of highways and other key infrastructure, to evaluate both the need for evacuation and the efficacy of particular evacuation routes. By combining risk and vulnerability data, GIScience permits the pre-event determination of those locales most and least likely to suffer destruction from multiple scenarios of different hazard events, enabling the better staging of disaster recovery resources. High levels of physical vulnerability—such as along coastal beaches—often do not correspond with high levels of socioeconomic vulnerability, thus detailed GIScience analysis may determine that residents occupying areas of medium physical vulnerability to one or more hazards may actually be the most vulnerable to disaster losses given their social vulnerabilities and lower levels of resiliency.

W

WALDSEEMÜLLER, MARTIN (CA. 1470–CA. 1522)

In 1507, on two maps of the world developed to accompany his *Cosmographiae Introductio*, Martin Waldseemüller included the name “America.” These maps were the first to use the name “America” for the southern part of the newly discovered Western Hemisphere, located in the middle of a land mass that would metamorphose during the 16th century into what we recognize today as South America.

The complete title of the first map, “Universalis cosmographia secundum Ptholomaei traditionem et Americi Vespucii alioru[m]que lustrations,” recognizes the work of the ancient Greek cartographer Claudius Ptolemy, as well as the reports of “discoveries” from 1497 to 1504 by the Italian navigator Amerigo Vespucci. It is not clear how much of the South American continent Vespucci actually visited, but his name was clearly placed in the center of the land area. Most significant in this recognition of Vespucci’s discoveries is the fact that he concluded that the land was not a part of Asia. Unlike Columbus, who was certain that he had reached Asia, Vespucci was convinced that this land was something else. Vespucci transmitted this view in a series of letters, and Waldseemüller mapped this perspective on the new maps. Within the context of the *Cosmographiae*

Introductio, this was a dramatic shift in the European worldview.

Waldseemüller’s partner in this work was Matthias Ringmann, who edited and amended the text of Claudius Ptolemy’s *Geographia* (the core of the *Cosmographiae Introductio*), a compilation of what was known about the geography of the world in about AD 150. Using the versions of *Geographia* published in Rome in 1478 and Ulm in 1482, as well as a Greek manuscript, Ringmann and Waldseemüller followed the modified text and original Ptolemaic maps with 20 new maps describing areas of the world not known 13 centuries earlier.

The first map was a modification of one of Ptolemy’s conic projections, extending the coverage of the Eastern Hemisphere to include all of Earth’s surface, except for the area in the Southern Hemisphere from 40° S latitude to the pole; however, the southern tip of Africa is carefully defined. As the knowledge base grew, maps created throughout the 16th century changed, with additions and modifications intended to make each one the most accurate and up-to-date representation. As new data emerged from the exploratory ventures to the New World (as well as eastward from the southern tip of Africa across the Indian Ocean), the maps of the world changed drastically (e.g., Mercator’s maps of 1538 and 1569).

The title of the map, “World Description According to Ptolemy and the Travels of Americus

Figure 1 The world according to Ptolemy and the travels of Americus Vesputius and others

Source: Original map in the collection of the Library of Congress, Geography and Maps Division. Hand-colored version reprinted with permission of the author from Whitfield, P. (1994). *The image of the world: 20 centuries of world maps* (pp. 48–49). San Francisco: Pomegranate Artbooks.

Vespucius and Others,” makes clear the cartographer’s intention: to create a new world map from the most up-to-date resources (see Figure 1). Waldseemüller’s second world map, composed of 12 globe gores, also includes “America.”

In subsequent maps, Waldseemüller replaced the name “America” with “Terra Nova.” Relying on the latest and most substantive information available, he did not employ the name “America” in his revised edition of the map in 1513. This revision provides little explanation about the resources that were used. In the *Carta Marina* of 1516, however, there are extensive explanations of the map content. It is important to note that the *Carta Marina* employed a cylindrical projection with a format like that of the portolan style navigation charts employed during this period.

While Waldseemüller did not use the name “America” on his later maps, and others acted similarly, enough world maps from the period continued to use it (e.g., Peter Apian’s map of 1520, which looks very much like Waldseemüller’s map of 1507). German and Dutch cartographers were instrumental in firmly establishing the use of the term. Waldseemüller produced other maps, all developed on the principle of obtaining and organizing the most reliable and up-to-date information.

As for the “Universalis cosmographia secundum Ptholomaei traditionem et Americi Vespucii alioru[m]que lustrations,” of the 1,000 copies that were printed, only one remains. It is on permanent exhibit at the Library of Congress in Washington, D.C.

WALKER, RICHARD (1947–)

A longtime professor of geography at the University of California, Berkeley, Richard Walker has played a significant role in Marxist theorizations of economic geography, agriculture, water and the social construction of the environment, and urban change. A student of David Harvey, Walker completed his PhD at Johns Hopkins University in 1977. With more than 80 refereed articles and four books, his work has been influential in several domains of human geography. He has long insisted eloquently on the centrality of the production process, the division of labor, and the politics of the state as driving forces behind numerous social and spatial phenomena under capitalism. He has also written on geographic pedagogy, particularly the challenges of teaching political economy. He has been actively involved with the journal *Antipode*, serving as its editor from 1991 to 1999. In addition to his research, Walker has mentored a number of successful PhD students, including Michael Storper.

Walker’s early works centered on the dynamics of American suburbanization, which he recast in light of the changing urban division of labor in the late 19th century rather than as an accumulation of individual residential location decisions. A series of papers and book chapters embellished this theme so often framed in empiricist and idealist terms. Thus, he maintained that suburbanization was not a “crabgrass frontier” but, rather, the reflection of long-standing industrial decentralization, real estate speculation, and the active promotion of business and government elites.

His other works in economic geography include powerful critiques of technological determinism; analyses of the relations between class, space, value, price, and profit; theorizations of uneven spatial development; assaults on behavioral perspectives of the firm; and an analysis of services as part of the broader logic of commodity production rather than a postindustrial utopia with their own, independent dynamics. *The Capitalist Imperative*, coauthored with Michael Storper in 1989, is widely heralded as one of the discipline’s most concise explications of the national division of labor and its consequences. Similarly, Walker and Sayer’s *The New Social Economy* in 1992

aptly summarized structuralist accounts of changing job patterns, technological change, and state policy.

He has also spent decades studying the historical development of California. Specific lines of thought within this topic include the geopolitics of water in the state, particularly the powerful role played by agribusiness. Walker also wrote extensively about the development of the greater San Francisco Bay area, its historical transformations, its changing social and spatial features, its struggles over green spaces, and its ongoing globalization.

WAR, GEOGRAPHY OF

History and contemporary events have demonstrated that there is a ubiquitous and fundamental link between geography and military operations of all types (i.e., peacekeeping through war). The relationship between warfare and factors of

geography such as terrain, weather, climate, and elements of the human landscape has always been evident. Likewise, the essential geographic concepts of location, time, space, and distance have a profound influence on military operations. Thus, military geography is defined as the application of the geographic discipline—its information, principles, tools, methodologies, and technologies—to the organization and implementation of the full spectrum of military operations.

Analytical Framework

Its publications, theory, and practice of war suggest that, at its core, military geography examines the characteristics of the environment within which military operations take place and that operations are influenced by the uniqueness of the natural and human landscape within diverse regions. The sum total of the geographic characteristics of a place is called a military operating environment. This is important because the development of a military strategy involves the selection of objectives, the deployment of forces, a method and sequence of employment, and the movement of military power to an area. Consequently, every phase of a military operation is subject to the effects of terrain and the elements of the natural landscape, the pervasive influence of weather and climate, and the elements of the human landscape. Hence, specific characteristics of places can be linked systematically with their effects on military activities, and the characteristics and effects can be correlated to regions. These effects are to some extent predictable, manageable, and can be useful in planning military operations.

Military Operating Environments

The study of geography demonstrates powerfully that places matter and that each place has unique characteristics. Military geographers think of places as operating environments, each exclusively influenced by the interrelationship of a discrete set of geographic variables. Karl von Clausewitz called the operating environment “terrain” in his famous 1832 treatise *On War*. In von Clausewitz's view, the environment is composed of the sum of the land and its inhabitants. Like von

Clausewitz, other strategists indicate that the operational significance of the environment varies with the mission, technology, and current circumstances. So too, then, must a geographic assessment of a military operating environment. Consequently, military geographers link geography and military operations by asking three fundamental questions: (1) What is the environment like? (2) Why is it like this here? (3) How will it shape the operation?

Thus, the *military operating environment* is the aggregate of all factors of the landscape that shape and control the ebb and flow of military operations, and in the final analysis, an examination of the operating environment typically results in an assessment of the following:

- Key terrain: strategic areas and selected critical objectives
- Surface structure: movement corridors and terrain compartments
- Weather and climate: effects on humans, machines, and operations
- Transportation networks and nodes
- Resources
- Logistical requirements
- Human landscapes: population, ethnic groups, urban zones, and cultural considerations

The Environmental Matrix

Military plans must be considered based on the advantages and limitations afforded by the geographic characteristics of the operating environment. In a wartime context, the purpose of any strategy is to weaken or destroy the enemy's ability to resist and to enable the fulfillment of stated objectives. To this end, distinctly different strategies have been pursued throughout history. The fundamental military strategy is the employment of military force to cause an enemy to capitulate completely. At the other end of the spectrum, people may employ a more limited approach, in which destruction of the enemy is thought to be impossible because political aims are restricted or because military power is inadequate. Insurgent forces use this form of strategy to prosecute their objectives: They employ military force at selected times and places with the objective of wearing down their opponent. Nonetheless, regardless of

the strategy, the success of a military operation depends on a reliable plan that takes into account a cogent analysis of extant geographic factors in a military operating environment.

Hence, the foundation of a geographic analysis of the operational significance of a region and its characteristics is called the *environmental matrix*. The environmental matrix is defined as the sum of all factors that operate at a place and that can have an effect on the successful implementation of any operation. The environmental matrix includes both natural and human components and assumes that the operating environment is the manifestation of their combined effects. The matrix, however, is only a methodology for analysis and is *not* predictive. Furthermore, because the landscape is not static and the context and objectives of military operations vary over time, care must be taken to reevaluate significant elements of the matrix continuously. An example of an environmental matrix is given in Figure 1.

Scales of Analysis

Variations in the size and scope of military problems demonstrate the need for military geographic analyses to be conducted at different spatial scales. In a military sense, scale is translated into military operations at the strategic, operational, and tactical levels—or for simplicity, macro- and microgeographic scales.

At the macro scale, military strategy is the method of employing military power to secure a national objective: Consequently, strategic military geography narrows down to the collection, compilation, analysis, and interpretation of geographic data for use in the preparation of war plans or plans to support national-level military operations other than war. Within this context, the principal concerns of strategic military geography include strategic mobility, accessibility, networks, resources, and vulnerability.

At the microgeographic scale, tactical military geography is the translation of geographic information as it relates to the employment and movement of military units during battle. Therefore, military geography at this scale is highly detailed and is typically directed toward the study of military characteristics of discrete types of terrain and geographic conditions and the development

Figure 1 Sample environmental matrix

Source: Author.

of plans to exploit those conditions. Tactical military geography includes the structure of terrain, elements of the natural landscape, conditions in the atmosphere, and the direct influence of the human landscape on operations. The manifestations of the military operating environment at the micro scale can generally be expressed as (a) observation, (b) cover and concealment, (c) mobility, (d) communications, (e) navigation,

and (f) human imprints on the battlefield and rules of engagement.

Approaches to Military Geographic Analyses

The existence of interactions between military environments and operations clearly requires methodologies and approaches that enable cogent

analyses of their potential influence on success or failure. Hence, military geography analyses can be grouped into three formal categories: systematic, topical, and regional.

In a military context, systematic geography engenders the application of systematic sciences such as geomorphology, climatology, and meteorology to the accomplishment of military operations or solving military problems. The full scope of systematic sciences that support military geography ranges between social and physical sciences, with widely divergent geographic subjects such as oceanography, meteorology, demography, biogeography, medical geography, and pedology, to name a few. Topical military geography serves to link systematic sciences to military science and focuses on the application of scientific knowledge to solve basic military problems. For example, data developed by geomorphologists, climatologists, biogeographers, and pedologists can be examined in the context of cross-country mobility to demonstrate the effects of slope, vegetation, and soil conditions on the ability of various military vehicles to cross a given landscape. Thus, topical military geography accounts for the differences imposed by diverse environmental conditions (e.g., deserts, forests, weather) on various types of military operations.

Similar to its role in academic geography, regional military geography assimilates the various characteristics of discrete formal or functional regions into an integrated study. Thus, the examination of military geography from a regional perspective should provide an integrated assessment of a formal region, such as a theater of operations, or a functional region, such as a terrorist network. Military geographers have developed regional study into a highly specialized and detailed methodology called *area analysis*. Area analyses stand out as mission-oriented studies in that they form the basis for a systematic interpretation of geographic conditions on a proposed course of action.

The Evolution of Military Geography

Linkages between geography and war and the exploitation of geographic information to support military affairs have likely existed for many millennia. Accordingly, military geography has

evolved since its formal beginnings in the 19th century, with developments in theory and methods of warfare, technological innovations, changes in the global strategic situation, and extension of areas of military interest. Early military geographies (e.g., Theophile Lavallee, *Géographie Physique, Historique et Militaire*, 1836, and Albrecht von Roon, *Militarische Landerbeschreibung von Europa*, 1837) were highly descriptive regional catalogs of data and chorographic descriptions of terrain, but they typically lacked incisive analyses. As an academic discipline, military geography essentially reached a contemporary zenith during World War II and the Cold War as a great deal of research was focused on supporting a global war and the important geostrategic conditions of the postwar world. During this era, military geographers not only included traditional assessments of military environments and regions but also saw the introduction of sophisticated analyses of the technologic requirements to support military operations and the geopolitics of global conflict. The Vietnam War and the period immediately following that conflict represent the nadir of academic military geography in the United States. This demise was caused largely by the social and political upheaval that occurred in its aftermath, which found its way onto American campuses.

Military geography, however, has experienced a renaissance and has perhaps achieved a new acme during the period following the Cold War, especially among academic geographers. The de facto strategic partitioning of the world by the two major superpowers effectively ensured that conflicts between client states were limited and that the bipolar strategic scenario was essentially stagnant for many years, thus restricting the nature of military geography. The new global situation has triggered a series of widespread developments in military affairs, and this expansion of areas of military interest has revitalized military geography. An examination of recent publications indicates that the discipline has expanded its scope well beyond traditional analyses of the terrain, weather, climate, and elements of human landscape as they pertain to warfare and violent conflict. Indeed, as the scope of military operations has expanded because of formerly nontraditional uses of military forces, such as humanitarian support operations, so too has the scope of military

geography evolved. Contemporary events such as ethnic warfare, environmental change, and global terrorism have forced an expansion of military geography as well. Today, research efforts have been extended to areas such as environmental security, security landscapes, the geography of ungoverned space, strategic chokepoints and piracy, energy and water resources, disaster relief, global-warming scenarios, and more effective analyses of latent ethnic divisions that have erupted into violent conflict following the end of the Cold War.

WASTE INCINERATION

Waste incineration is a waste disposal method that can be used to combust a range of materials classified as municipal solid wastes and hazardous wastes. Incinerators, sometimes referred to as thermal treatment plants, convert wastes into steam, gas, heat, or ash (those that produce a source of energy are often known as waste-to-energy plants). Waste incineration is a contentious and emotional issue. Geographers and other social scientists have explored many conflicts associated with waste incineration. Following a brief review of the history of waste incineration,

some of the key conflicting issues are highlighted in this entry.

Waste incineration, or the systematic burning of waste, has been taking place for a little over a century. It is recorded that the first incinerator was established in the United Kingdom in 1874 and the first waste-to-energy plant was developed in the mid 1890s. The United States had more than 600 municipal waste incinerators in operation during the 1930s. Incinerators at that time employed low-level technology, and they functioned with limited control over the waste mix that entered the facility or the emissions that were produced by the combustion process. Mounting scientific evidence about the issue of human health hazards and environmental contamination led to growing public concern about the practice in Europe and North America from the 1950s onward.

Since the 1970s, tough national and transnational levels of emission controls have encouraged improvements in incinerator technology. Indeed, the 1980s and 1990s have seen a resurgence of interest in incineration as a waste management option because of enhanced levels of profitability, improved design, and a growing consensus for the need for energy supplied from non-fossil-fuel sources.

Some of the key arguments proffered by the proponents of incineration include the following:

- Incineration emissions are insignificant relative to total air pollution in developed economies, and any emission problems can be solved technologically.
- The generation of energy from incineration preserves nonrenewable fuels and therefore contributes to a net reduction in greenhouse gas emissions.
- Energy recovered from incinerators can serve as a revenue source.
- The volume of waste is reduced by as much as 90% and may extend the available landfill space.
- Incinerators offer geographical concentration of waste in comparison with other, more dispersed options such as landfills.
- No significant alterations to waste collection practices are required, and the construction, management, and operation of incineration plants can be carried out by the private sector, reducing potential tax burdens.

However, incinerator facilities and proposals for such plants have faced opposition from local communities in most countries in Europe and in the United States for at least the past 25 years. Some of the main arguments put forward by the anti-incinerator lobby include the following:

- The incineration process releases dioxins and furans into the air, resulting in possible risks to human health as well as to the environment.
- Incineration simply transfers contaminants from one medium to another (from the ground to the atmosphere).
- The release of contaminants into the atmosphere cannot be controlled in comparison with containment in a landfill.
- Incinerator plants are costly to construct relative to other waste management options.
- Ash produced from the incineration process still needs to be disposed of.
- The incineration process requires paper and other combustibles, competing with and detracting from recycling and waste minimization programs.

Geographers and a range of social scientists have produced a large body of research exploring contentious issues such as community responses to waste incinerator facilities, risk communication for incinerator siting, the technical processes of risk analysis and public perception of risk associated with incinerators, and the impact of waste disposal facilities on housing prices. One of the most important areas of research to emerge in relation to incineration conflicts has been the social and environmental justice movement. The uneven spatial location of waste infrastructure has been well documented. Often waste facilities tend to be located in areas that are characterized by remoteness, areas with peripheral communities, areas with economic marginality, areas with political powerlessness whose people have a culture of acceptance, and areas of existing environmental degradation. Community opposition to waste management infrastructure, such as incinerators, has given rise to many phrases, including “not in my backyard” (NIMBY) and “locally unwanted land uses” (LULUs). A key extension of this opposition has moved from NIMBY to NIABY (“not in anyone’s backyard”) as the objection is often based

not only on self-interest but also on wider social and political issues. These include general environmental concern, dissatisfaction with the consultation process, and distrust of decision makers.

It has been argued that while older incinerators were responsible for air pollution, more modern waste-to-energy plants claim to have rectified this problem by incorporating better pollution control technology and improved combustion processes. The common goal of all modern waste-to-energy plants is the production of an essential product—energy.

Many people consider incinerators a better waste disposal method than the traditional dumping of wastes in sanitary landfills, and they are commonly used in countries such as Japan, where land available for landfills is scarce. Despite the controversial image of incinerators, current research generally concludes that there is a place for incineration provided that it is part of an integrated waste management plan and that it incorporates strong waste prevention, waste minimization, and recycling programs.

WASTEWATER MANAGEMENT

Any water whose quality has been affected after being used by human-related activities is considered to be wastewater. Therefore, wastewater management is intrinsically related to water quality

management. Its definition can be broadly summarized as the activities that a person or a group of individuals or entities carries out to protect public and environmental health from the adverse effects of contaminants found in wastewater. Managing wastewater encompasses several important areas that can be summarized as follows:

- The collection and transportation of the wastewater away from highly populated or environmentally sensitive areas via sewerage networks (sewerage is the infrastructure used to collect and transport wastewater, including pipes, pumps, screens, channels, and combined sewer overflows, used to move sewage from its origin to the point of eventual treatment or disposal)
- Treatment prior to discharge
- Releasing wastewater again into the environment (land, rivers, lakes, and oceans) or reusing the treated wastewater for beneficial purposes (e.g., cooling of power-generating facilities, groundwater recharge augmentation)
- Ensuring that the concentrations of contaminants found in the receiving water bodies or land do not harm people and the environment

Sources of Wastewater

Wastewater is collected in sewerage networks (if available) or in small decentralized systems such as privy houses, pit latrines, septic tanks, and so on. Most cities throughout the world have sewerage systems that allow for the collection of both wastewater and runoff resulting from rain. Runoff carries a mixture of water, sediments, oil, and grease from streets that is combined with wastewater from human-related activities that produce liquid wastes. Sources of wastewater from human-related activities are classified as point source or direct, and nonpoint source or diffuse. Examples of direct sources are the discharges from domestic residences, public properties such as governmental buildings, private commercial properties, industrial and mining facilities, and livestock farms. Examples of diffuse sources are agricultural areas. Each of these

sources can add different types and concentrations of contaminants to water.

Wastewater Constituents

Wastewater is composed primarily of water. Alongside water, there are high concentrations of chemicals, toxic compounds, and organic and inorganic matter. When wastewater is accumulated and is left untreated, the decomposition of the organic matter that it contains leads to nuisance conditions, including the production of malodorous gases. Untreated wastewater contains a large number of pathogenic organisms (bacteria, viruses, parasitic worms, etc.) that come from human and animal intestinal tracts. These organisms are the leading causes of epidemics such as typhoid, cholera, hepatitis A, dengue fever, among others and bacteriological and viral diseases. Wastewater also contains nutrients, such as nitrogen and phosphorus, that exist naturally in the environment. However, the high concentrations of these nutrients in wastewater can stimulate unwanted growth of algae and other aquatic invasive species. Wastewater may also contain heavy metals and different types of toxic compounds that are known carcinogens. Because of these reasons, the highest priority of wastewater management has been to adequately remove potential nuisance conditions that can severely affect public and environmental health.

Brief History

Wastewater problems are very old. But it was not until the mid to late 18th century that management of water quality and wastewater began. Events such as the Broad Street cholera epidemic in London led to the enactment of the first regulations to protect public health and drinking water from wastewater discharges. The “sanitary idea” of Edwin Chadwick in London proposed that wastewater must be collected via sewerage networks away from the highly populated centers and the community water supply sources. The collected untreated wastewater was then discharged untreated into water bodies further downstream of communities. Engineers during these times favored the construction of drinking water treatment plants instead of having to

spend money in treating wastewater prior to its being discharged.

Concern for the pollution of rivers resulted in the creation of the first type of surface water quality standards, the “dilution standards,” which are still used today in combination with what are known as “end of pipe” effluent standards (for wastewater treatment plants, or WWTPs), and ambient water quality standards for the protection of river basins.

Broad irrigation and intermittent filtration of wastewater on land were the first known types of treatment other than discharging untreated wastewater into water bodies. Intermittent filtration was the first step in the development of sewage treatment techniques that involved the biochemical oxidation of the organic matter. In the late 19th century, several methods of sewage treatment were developed and tested. Examples of the new technologies developed in that period were the contact and trickling filters developed by Joseph Dabdin and the septic tank developed by Donald Cameron. Modifications to the Cameron septic tank later followed (Travis tank, Imhoff tank, etc.). Modern technologies evolved from these simple but effective wastewater treatment systems.

Modern Approaches

Countries throughout the world have followed similar approaches in establishing policies and regulations for the management of wastewater, each with different levels of success. For example, the United States and Mexico have almost identical regulations for managing wastewater, but due to heavy financial burdens for operation and maintenance costs, as well as costs of monitoring and control of wastewater discharges, Mexico’s wastewater treatment coverage is much less than in the United States. Other countries in Latin America such as Brazil and Argentina have wastewater management programs similar to those of the United States and European countries such as Germany, the United Kingdom, and France.

Many of these less developed countries have enacted regulations that emulate those of the more industrialized and developed nations. Examples of some of the wastewater management regulations include the application of point source standards or end-of-pipe regulations, requiring

discharge permits, wastewater quotas, incentive programs to reduce nonpoint sources of pollution, and also the application of ambient water quality standards. Figure 1 summarizes the wastewater management process. Within each section, there are major issues to be addressed. For instance, the collection and transportation of sewerage is an important topic of hydraulics in the field of civil engineering.

Figure 1 Simple diagram of the wastewater management process

Source: Author.

Wastewater Treatment

Wastewater collected in sewerage systems is commonly treated at large-scale WWTPs. However, for many communities, this practice is not cost-effective or practical. These latter communities rely on what are known as onsite wastewater treatment systems (OWWTS). All treatment methods have been classified into two categories. Methods in which the applications of physical forces are used to remove pollutants are known as “unit operations.” Methods of treatment in which chemicals or biological reactions are applied are known as “unit processes.” These two groups of methods are often applied simultaneously. Several levels of treatment can be attained, depending on the target goals desired. The levels of treatment are preliminary, primary, secondary, and tertiary (or advanced).

The most common treatment is an aerobic system called the activated sludge process. This wastewater treatment process is based on the recirculation of a biomass composed of microorganisms that are able to absorb and adsorb the organic matter carried in the wastewater. Other types of treatment may include ecological approaches using reed bed systems such as constructed wetlands. Modern systems include tertiary treatment by microfiltration or synthetic membranes. These advanced treatment systems, however, are very expensive, and their use has been limited. As the membranes required for advanced treatment become less expensive, these methods will become more popular.

WATER DEGRADATION

Water is a “renewable” resource that provides essential services, is constantly restored by the hydrologic cycle, and can be degraded when used or altered faster than it can be replenished. Freshwater degradation occurs when the physical, chemical, or biological characteristics of water become harmful to the environment or organisms, including humans, by which the usefulness of the water resource is in some way reduced. The quality of water as a resource, and therefore the acceptable level of degradation, depends on the intended use of the water and consequently also depends on the desires of multiple, often conflicting stakeholders. The globally variable distribution of water resources, the burgeoning human population with increasing consumptive uses, and increasing waste production and pollution make water degradation an important societal and ecological concern. This entry discusses the sources, distribution, and use of freshwater; water stresses, causes, and drivers; indicators and assessment of water degradation; and water degradation prevention measures.

Sources, Distribution, and Uses of Freshwater

Water covers about 70% of Earth's surface area; 97.5% of this is saltwater, contained mostly in oceans and seas, and 2.5% is freshwater. Most freshwater, about 68.7%, is frozen in ice caps and glaciers, 30.1% is stored as groundwater, and the remaining small fraction (<1%) is found as surface water in lakes and rivers, as soil moisture, and in the atmosphere and biota. At any time, usable freshwater amounts to about 0.01% of the world's total water. The world's continents receive an estimated annual precipitation of

Plastic and trash pollution in Bicz Lake, Romania

Source: Stéphane Bidouze/iStockphoto.

110,000 km³ (cubic kilometers), which is variably distributed by ecological region.

Although we have enough water at a global scale, the distribution of freshwater has been a problem. P. Gleick indicated in 1993 that two thirds of the world's population lives in areas receiving only one quarter of the world's annual rainfall. The global freshwater demand per capita is rising substantially as a result of economic development and population growth. Agriculture represents 70% of the global annual freshwater use (FAO-AQUASTAT). Meeting the rising water demands and the increasing reliance on irrigation to produce food will be a challenge for the growing population and for economic activity in the face of the decline in the finite freshwater resources and increases in pollution.

Water use can be classified as consumptive when water is physically removed for a specific purpose, such as public potable water supply,

irrigation, livestock, mining, and others. Non-consumptive uses include hydroelectric power generation, fisheries, navigation, environmental flow, and others that require a certain amount of water at a given point and time but that do not necessarily remove water from its source.

Water Stresses, Causes, and Drivers

The degrading factors that influence water quality can be chemical, biological, or physical, often with compounding interactions among these three causes.

Chemical Water Pollution

Chemical water pollution is the reduction of the usefulness of water by contamination with one or more degrading substances, such as sediments, organic wastes, nutrients, metals, salts, and many

other natural and synthetic chemicals that can be caused by both anthropogenic (human caused) and natural processes. Humans have a great impact on water quality through their consumptive uses and also in the generation of pollution. Several components of the hydrologic cycle can also affect the quality of water; for example, evaporation from surface pools can concentrate salts and other chemicals by reducing the overall water volume, and runoff and infiltration can leach harmful levels of metals into groundwater. Degradation of water quality due to processes in the hydrologic cycle is referred to as background pollution or natural contamination to distinguish it from degradation from anthropogenic causes.

Sources of pollutants can be classified as either point or nonpoint sources. Point sources are generally categorized as contamination coming from a discrete source, such as a discharge pipe. Point sources are generally easy to identify, have quantifiable discharges, and have readily evident environmental impacts; examples include industrial effluents, wastewater treatment plants, landfills, and abandoned mines. Nonpoint sources are generated from broad and diffuse sources that can be difficult to identify and quantify. Examples include agricultural and urban runoff. The pollutants from nonpoint sources enter water bodies by surface and groundwater movement and from the atmosphere in the form of precipitation (e.g., acid rain). Nonpoint source pollution accounts for the major sources and causes of water degradation globally.

Biological Pollution

Biological pollution of water resources has mostly been identified with waterborne diseases that include infectious hepatitis, cholera, bacterial dysentery, and microscopic parasites such as *Giardia* and *Cryptosporidium*. Many of these diseases are associated with the presence of raw or improperly treated sewage or animal wastes that get into a drinking water resource. Improvements in wastewater treatment have reduced or eliminated most cases of waterborne infectious diseases in developed countries, but these diseases continue to be widespread in undeveloped nations. Discharges of organic matter, such as sewage, pulp mill effluents, and animal processing wastes, can affect water quality by creating an oxygen demand. Aerobic

(oxygen using) waterborne bacteria consume the available dissolved oxygen (DO) during the decomposition of organic matter, reducing DO to a level insufficient to support other oxygen-breathing aquatic organisms (e.g., fish) and making the water unfit for human consumption. The measurement of the oxygen demand needed to satisfy the decomposition of organic matter is called the biological oxygen demand (BOD).

Eutrophication

Eutrophication is a widespread problem and exemplifies the interactions between chemical pollutants and biological processes to degrade water quality. Eutrophication is the process whereby a water body accumulates nutrients (mostly nitrates and phosphates) that are essential for, and often limit, the growth and proliferation of algae and other aquatic plants. Eutrophication is a natural process (natural eutrophication) that occurs when nutrients leach from soils or erode from rocks. However, anthropogenic activities, mostly associated with the use of agricultural fertilizers, have greatly increased the rate at which water bodies are becoming eutrophied (cultural eutrophication). Algae proliferate (bloom) and use the excess nutrients, fixing atmospheric carbon dioxide (CO_2) into organic matter in the form of new algal cells. As these cells die and decompose, they create a BOD that leaves little DO to support other aerobic aquatic organisms (e.g., fish).

Physical Factors

Water control and supply projects have been in use since ancient times and have led to numerous human-benefitting results, including economic growth and food production. Structures such as dams, reservoirs, and distribution systems can support urban and agricultural development but often have severe ecological consequences. Dams and reservoirs can degrade the ecological usefulness of the water by reducing stream flows, halting nutrient and sediment delivery, blocking fish migrations, and destroying habitats.

Water Stress

Water stress is mainly caused by overtapping of available water resources without considering

sustainability or following few or no water and soil conservation practices to augment groundwater recharge and reduce runoff. Overpumping of groundwater is often associated with salinization of groundwater in coastal areas. Salinization is the increase in soluble salts in the water due to various factors. The increased use of chloride salts in roads during winter and overpumping of groundwater in coastal areas, which leads to the lowering of the piezometric surface (saltwater intrusion), are the major sources of salinization. Some surface irrigation practices in arid regions can also increase salt accumulation on the surface of irrigation fields and hence increase the salinity of the receiving water bodies during runoff.

Thermal Pollution

Thermal pollution is water degradation due to the alteration of the temperature of the water and is also a common problem, especially for aquatic organisms. Currently, the main source of thermal pollution is using water as a coolant in electrical power generation and other industrial manufacturing plants. These processes increase the temperature of the receiving water bodies, reducing the available dissolved oxygen, and stressing aquatic organisms. In some instances, such as the release of deep cold water from a dam, the temperature of water bodies decreases, which can also stress warm-water organisms.

Indicators and Assessment of Water Degradation

It would often be difficult and expensive to conduct complete analysis of the numerous factors that can potentially degrade water quality. Often, water quality indicators are used to assess if water is fit for a desired use. These assessments range from simple field measurements to complex laboratory analysis requiring standardized protocols. The extent of water degradation often does not become apparent until water quality indicators fall below set standards. Standards are developed for the intended purpose or use of the water resource—such as drinking water, safety of human contact, fishing, navigation, and ecosystem health. Water bodies that

fall below standard values are classified as polluted or degraded for that purpose.

The most commonly used water degradation indicators for domestic use of water are taste and odor, alkalinity, pH, dissolved metals, dissolved organic substances, salts, metalloids, microorganisms, heavy metals, and others. Chemical indicators of water degradation for environmental use include alkalinity, pH, dissolved oxygen, chemical oxygen demand, biochemical oxygen demand, nitrate, phosphates, and pesticides, while physical assessments include temperature, turbidity, and total suspended solids. Biological assessments, often using indicator organisms (e.g., total coliform as an assay for many pathogenic bacteria), are also commonly used to characterize water bodies intended for domestic or environmental use.

Water Degradation Prevention Measures

The hydrologic cycle and the environment through which water travels contain many chemical, physical, and biological processes that assist in decreasing the mass and concentration of harmful materials. Examples include the biodegradation of organic and synthetic wastes and the sedimentation of metals. This natural attenuation capacity depends on the form and residence time of the water; that is, flowing water generally has a greater ability to self-cleanse than does groundwater. However, water quality suffers when the rate of degradation exceeds this attenuation capacity. The most effective methods of reducing water degradation are to identify and lessen or eliminate the causes if possible. This often involves land management procedures termed *best management practices* (BMPs). BMPs include practices such as replacing water-demanding crops with dry-land (xeriphytic) crops to reduce water consumption and decreasing excess nutrient runoff from agriculture by using less fertilizer and more conservative cropping systems.

WATER MANAGEMENT AND TREATMENT

Scientific water management is a relatively new branch of science. Yet proper use of water resources and their management and treatment (widely understood as preparing the water for various purposes) are inherently connected to development and civilizing societies on Earth. This field has recently come into prominence because of the increased water demand related to global population growth and more intense use among almost all social and industrial sectors. Compounding this, global warming and climate change scenarios on Earth forecast that water resources will diminish in many places, while intensified extreme phenomena (e.g., floods or droughts) will render the proper distribution of water resources more difficult. The diminishing quantity and quality of available water resources generate the need for their better treatment. This requires new investigation of alternate treatments such as new methods for collection precipitation or improved methods for the desalinization of seawater.

Water Management

Water management is usually supervised by governments through designated governmental agencies. Their main task is to ensure an adequate quantity and quality of water for the use of people, society, and the economy. In many countries, the institutions that are set up to supervise water management also deal with the protection of water against pollution and the protection of a country's territory against floods. Because the issues of water management are of vital global importance, many have broader implications and must be dealt with at the international level. For example, European Union member states act collectively under the "Water Framework Directive" or the "Flood Directive." International cooperation in this field is also carried out by the United Nations Educational, Scientific and Cultural Organization (UNESCO). Specialized nongovernmental organizations have also been playing a vital role recently in influencing the decisions taken in the field of water management.

Water Resources

Water belongs to the category of "depletable natural resources"; at the same time, it is also considered one of the "renewable resources." There are three basic groups of resources for meeting water needs (Table 1):

1. Atmospheric precipitation and deposits
2. Underground waters at deep water-bearing layers (with no direct recharge of surface waters)
3. Surface waters (river runoff comprising surface and shallow ground runoff)

Water Needs

Water needs are determined by the quantity of water necessary for the human population and for the functioning of those sectors of the economy that are active in a given area (region, country, continent): agriculture and forestry, industry, electrical power generation (especially hydroelectric power generation), municipal economy, and inland ship and cargo transport.

Continent	Area (million km ²)	Population (millions)		Water Resources (km ³ /yr.)				Potential Water Availability (1,000 m ³ /yr.)		
		2007	2050	Average	Maximum	Minimum	Coefficient of Variation	Per 1 km ²	Per Capita in 2007	Per Capita in 2050

Figure 1 Total renewable freshwater resources per capita (cubic meters per person): long-term annual average

Sources: Data from EUROSTAT (Statistical Office of the European Communities), FAO (Food and Agriculture Organization), OECD (Organisation for Economic Co-operation and Development), and UNSD (United Nations Statistics Division). Map from UNSD Environmental Indicators, “Water Resources: Long-Term Annual Average.” Retrieved December 8, 2009, from <http://unstats.un.org/unsd/environment/waterresources.htm>.

It is estimated that the minimum quantity of water required for a person to drink, to use for sanitary (hygienic) purposes, and to support agricultural cultivation is 1,000 cubic meters (m³) per year (Figure 1). Existing world water resources are estimated to be sufficient to cover the minimum needs of 42.8 billion people, a figure more than six times the world population in 2007. The world's population is estimated to grow to 9.3 billion people in 2050, at which time there will still be 4,600 m³ of water available for each inhabitant of Earth (Figure 2). However, it has to be borne in mind that these figures only deal with quantity and that at present a considerable fraction of available water resources requires costly treatment.

In the future, water quality may be expected to deteriorate significantly (especially in many densely populated areas of our planet), so the actual availability of pure water may become limited. Moreover, water resources are very unevenly distributed across Earth. There are large

differences in supply and demand even within a given country or continent.

Water can be used by water *consumers* (who use it up, e.g., for agriculture and forestry, industry and heat engineering, or the general municipal economy) and also by water *users* (who take advantage of water resources without using them up, e.g., for hydroelectric power generation, inland ship transport, and water tourism and recreation). According to different estimates, around 67% of world water is used by agriculture, 20% to 25% by industry, and the rest by the municipal economy. Of course, the distribution in a particular country depends on the environmental conditions and the degree of economic and social development in that country.

Water Treatment

Chemically pure water is never found in nature. Being one of the best solvents, water contains

Figure 2 Potential water availability in 2007 and 2050

Source: Author.

not only hydrogen and nitrogen but also a large variety of contaminants, both chemical and bacteriological. These substances may be dissolved in water or form suspensions. Because water is a perfect habitat, it can also contain microorganisms. The products of human activities, such as agricultural and industrial waste and sewer water discharge, cause a number of pollutants to enter the water. Some contaminants can be determined organoleptically by evaluating the color, turbidity, and density of particulate matter. The most widespread chemical contaminants are metals, including manganese, aluminum, lead, zinc, and copper. The nonmetals, such as nitrate, fluoride, and phenols, appear less frequently. However, agriculture and municipal economic reasons are the cause of increasing contamination of water resources by nitrates, pesticides, herbicides, and

polychlorinated biphenyls. Microorganisms can be primarily found in water in the form of bacteria and viruses.

All these reasons explain why it is necessary to purify water. Water treatment is the process of bringing water to the state required for a specific purpose. Different processes are used depending on the end use; some processes adjust underground or surface water to make it suitable for drinking purposes, while other processes are used to adjust contaminated water (e.g., from underground mine workings) to satisfy cooling needs in conventional power plants.

Some water purification processes employ physical methods, such as sedimentation or adsorption, while others use chemical and biological methods. In addition, potable water is disinfected by chlorination, ozonation, or UV radiation (Figure 3). Potable water has to meet

Figure 3 Potable water treatment process

Source: Author.

the requirements stipulated by state law. The World Health Organization, the U.S. Environmental Protection Agency, and the European Union provide guidelines stipulating the recommended (maximum and minimum) values of the various substances that drinking water should contain.

Water Management Problems

The principal challenges that water management agencies will have to face in the coming years include the following:

- Shortage of good-quality water (the lack of potable water and sanitary facilities is already an acute problem)
- Changes in the distribution of water resources connected with global climate change
- Natural disasters directly connected to water (floods) or causing damage to the existing natural or human-made water management infrastructure
- Conflicts caused by unequal access to water resources
- Deteriorating quality of water resources leading to higher treatment costs

Timeline of International Water Management Efforts

Today, water is considered one of the most important factors for sustainable development. The most important timeline of events that led to treating water as such is presented as follows. The majority of the documents supporting the timeline events are available through the United Nations Organization agencies.

1965–1974. The world's attention was first drawn to water issues during the International Hydrological Decade (1965–1974), initiated by the UNESCO. This program led to an unprecedented advance in the field of water science knowledge and cooperation.

1972. In this period, another important event took place—the United Nations Conference on the Human Environment—which produced an important declaration stating, “A point has been reached in history when we must shape our actions throughout the world with a more prudent care for their environmental consequences” (Declaration of the UN Conference on the Human Environment). The declaration made environmental issues a priority and set the stage for further investigation into water resources.

1977. The first intergovernmental conference focusing on water issues was held in Mar del Plata, Argentina. This “UN Conference on Water” resulted in the “Mar del Plata Action Plan” with recommendations covering all the essential components of water management.

Twelve resolutions covering a wide range of specific subject areas were also adopted, making it one of the most effective and productive meetings thus far assembled concerning the subject of water resources.

1987. Ten years later, the World Commission on Environment and Development (also known as the Brundtland Commission) published a report titled *Our Common Future*. This report shaped the guiding principles for sustainable development. Although the report does not expressly address water, it contains the most commonly quoted definition of sustainable development, which is also applied to water resources: “Humanity has the ability to make development sustainable to ensure that it meets the needs of the present without compromising the ability of future generations to meet their own needs.”

1992. Another advance on the sustainability path was the “Dublin Statement,” adopted by the International Conference on Water and the Environment. Its four principles are often quoted as the guiding principles of water resource management.

1992. The most comprehensive plan for global, national, and local actions in every area of human impact on the environment is Agenda 21, adopted by the UN Conference on Environment and Development meeting held in Rio de Janeiro, Brazil. Chapter 18 of the document is devoted to freshwater resources.

1996. On the initiative of water specialists and international organizations and in response to increasing concerns about world water issues among the global community, the World Water Council was established. Every third year, it organizes the World Water Forum, which is the largest periodic international event in the field of water.

2000. The UN General Assembly in New York created the Millennium Development Goals, aimed at ensuring environmental sustainability. The specific goals were to integrate the principles of sustainable development into country policies and programs, to reverse the loss of environmental resources, and to reduce by half the proportion

of people without sustainable access to safe drinking water by the year 2015.

2001. The Freshwater Consultation held in Berlin, Germany, produced two important documents: (1) the “Bonn Recommendations for Action,” focused on sustainable management of water resources, and (2) the “Bonn Charter for Safe Drinking Water.”

2002. The goal of the World Summit on Sustainable Development held in Johannesburg, South Africa, was to reinforce and fully adopt the Millennium Development Goals set out 2 yrs. (years) before. The “Plan of Implementation” of this summit includes actions related to water sustainability for the eradication of poverty and protection and management of natural resources for economic and social development. The conference also called for governments to develop integrated water resource management and water efficiency plans by 2005.

2003. In an effort to increase awareness of the importance of sustainable freshwater use, protection, and management, 2003 was designated the International Year of Freshwater. This coincided with the publication of the second *UN World Water Report*—a comprehensive review giving an overall picture of the state of the world’s freshwater resources and aiming to provide decision makers with the tools to implement sustainable use of water. This report is published every 3 yrs. and brings together the efforts of 24 UN agencies.

2005–2015. Today, we are in what has been proclaimed the Decade of Water for Life (2005–2015) by the United Nations. The primary goal of the decade is to promote efforts to fulfill international commitments on water-related issues, such as the Millennium Development Goals.

WATER NEEDS

Water needs are defined for the purposes of this entry as the requirements of Earth systems for water, and the entry specifically explores the interactions between humans and the environment in the use of water and the impacts of those uses on the functioning of Earth's ecosystems. The needs of Earth's ecosystems (including humans as a part of these ecosystems) for water are relevant both because water is an important aspect of human-environment interactions and also because water features, water availability, and water use are defining elements of place. Geography has a rich tradition of research on water and wetland ecosystems and human use of water resources. This entry addresses several aspects of water needs: the need of Earth's ecosystems for water, human uses of water, the impact of various human uses on water quantity and water quality, and the linkages between water and energy. In addition, it discusses the need for information and tools to better manage the world's water resources and the need for development of informed, effective water governance institutions to help alleviate potential

conflicts over this precious and increasingly scarce resource.

Water Needs of Earth's Ecosystems

The primary and most critical water need is the need for sufficient water at the appropriate time and in the required amount to sustain Earth's ecosystems, of which humans are a part and on which all life depends. As water moves through the hydrologic cycle, not only is water itself transported but also energy and materials are moved through their own biogeochemical cycles, habitat is provided for aquatic organisms, and terrestrial systems are sustained. Water and freshwater ecosystems provide numerous ecosystem services to people worldwide. Ecosystem services are the wide range of benefits provided to people through the functioning of Earth's ecosystems. This includes many types of services such as provisioning services that provide food, water, and fiber; supporting services such as transportation and cycling of materials; preservation services such as preserving plant and animal species; and cultural and aesthetic services that include social, economic, spiritual, and recreational benefits.

The allocation and management of water resources, especially in international river basins, are becoming more difficult. Increasing demands are being placed on human and environmental systems by competing water uses that include hydropower generation; flood control; agricultural, industrial, municipal, and industrial water use; flows for water quality; fish habitat and fish passage; and recreational and cultural uses. Competing interests for water are taxing the limited water supplies. The water needs of agriculture, industry, and urban areas compete with environmental claims for in-stream water or the water rights of indigenous people. Traditional water governance structures are not well suited to address the complex issues and needs of competing agents to resolve the emerging problems over water quantity and quality, nor are they flexible enough to address the projected rapid changes in the timing and delivery of water as the world's climate changes.

As part of the Pilot Analysis of Global Ecosystems, the World Resources Institute (WRI) assessed the condition, status, and trends in the world's freshwater ecosystems. WRI selected and

analyzed both quantitative and qualitative information and developed five indicators of the condition of the world's freshwater systems:

1. Human modifications of water bodies and watersheds
2. Water quantity
3. Water quality
4. Food (fish in particular)
5. Aquatic biodiversity

A major finding of this project was that the world's freshwater systems are so degraded that their ability to support human, plant, and animal life is greatly in peril.

Freshwater systems in general and wetland ecosystems in particular have been subject to serious degradation worldwide. Among the key findings of the Millennium Ecosystem Assessment (MEA) conducted by the WRI, United Nations Environment Programme, World Bank, and others were that wetland and freshwater systems have suffered greater and more rapid loss and degradation than other ecosystems worldwide and the condition of both freshwater and coastal wetland species is deteriorating faster than in other ecosystems. The authors of the MEA, which was released in 2005, identified population growth and increasing economic development as the primary indirect drivers of degradation and loss, and the primary direct drivers as infrastructure development, land conversion, water withdrawal, eutrophication, and pollution, as well as overharvesting and overexploitation of fisheries and other resources and the introduction of invasive alien species. Further key findings included the expectation for population growth and global climate change to increase the rate and extent of wetland loss, the incidence of waterborne diseases, and nutrient loading to freshwater and coastal systems. These impacts are expected to be severe and may result in the loss of many of the functions that we rely on wetlands and freshwater systems to provide, but they have been largely taken for granted until now.

Protection of these ecosystems and the services they provide is thus a critical element to consider as the world plans for the water needs of the next millennium.

Water Use

About 4,000 km³ (cubic kilometers) of water each year are withdrawn from freshwater systems for human use, an amount equivalent to about 20% of the base flow of the world's rivers. Groundwater withdrawals are estimated at approximately 600 to 700 km³/yr. (per year)—or about 20% of global water withdrawals. On a worldwide basis, agriculture withdraws the most water from surface and groundwater systems, with about 70% of water withdrawals worldwide used for irrigation. In the United States, the U.S. Geological Survey (USGS) has estimated that water withdrawals for energy production are responsible for the greatest amount of water used, with the quantities of water used for thermoelectric and thermonuclear power generation slightly higher than those withdrawn for agriculture. Human use of freshwater has altered both the amount of water delivered to rivers, streams, and wetlands and the timing of its delivery. These changes have resulted in the decline and even the extinction of freshwater plant and animal species and may impair the ability of freshwater ecosystems to sustain themselves.

Water scarcity now affects much of the world, according to the United Nations Comprehensive Assessment of the Freshwater Resources of the World. About 40% of the world's population—roughly 2.3 billion people—live in regions with a per capita water supply of less than 1,700 m³/yr. About 1.7 billion people live in river basins where water supply is less than 1,000 m³/yr., and nearly 10% of the world's population suffers from serious water shortages.

Water Quality

Water quality appears to have degraded worldwide with the growth of intensive agriculture and large urban/industrial areas. Water pollution is a major cause of death and disease in the developing world, although surface water quality has improved in North America and Western Europe with respect to some pollutants such as phosphorus and some pesticides. Nonpoint source pollution from agricultural runoff is still a concern, however, even in the richest nations of the developed world. The delivery of nitrogen to coastal

regions worldwide is expected to increase by 10% to 20% in the next two decades.

Water for Agriculture

In the late 1990s, irrigated agriculture accounted for 40% of the global food production, even though just 17% of the global cropland is irrigated. This reflects the disparity between the productivity of rain-fed systems versus irrigated systems. Agriculture is society's major user of water, withdrawing 70% of all water worldwide, according to the World Meteorological Organization.

Water and Energy

Water and energy are highly linked throughout the world. Water is both a source of electric power and a resource that requires energy to obtain or distribute to places where it is needed. The production of many forms of energy, not only hydropower but also thermoelectric and thermonuclear power, requires the use of water for cooling. Often, when people remove water from a river or stream for use, the water returns to that stream at a warmer temperature. In the United States, there has been a growing recognition of an "energy-water nexus," or an interaction between water and energy. Of the total electricity generated in the world, hydropower generated approximately 18% of the electricity used worldwide in 2006 and accounted for about 5% to 6% of overall energy use. There are 19 countries that rely almost entirely (90% or more of electricity generated) on hydropower for generation of electricity, including Brazil, Norway, Burundi, and Laos.

Water and Wetlands at the Land-Sea Margin

Nutrient pollution and the resulting algal blooms are more frequently observed in both inland and coastal systems around the world. At least 415 coastal areas have been identified by the WRI as experiencing some degree of nutrient enrichment; more than one third of the areas identified have been affected so severely that the oxygen concentrations in the coastal waters have become low enough (<2 parts per million) to be lethal to

marine organisms for a portion of the year. As a result of this nutrient pollution, primarily from agricultural runoff, more and more coastal regions are being affected by the zones of low oxygen concentration, threatening coastal and marine life and the associated fish and shellfish production from nearby fisheries.

The loss of coastal wetlands and the protection they provide to coastal ecosystems has been blamed for both the increased impact of eutrophication and the increase in damage resulting from the unmitigated wave and wind energy of hurricanes and tropical storms.

Restoration of coastal wetlands would protect valuable coastal regions that are presently vulnerable to damage from hurricanes, tropical storms, and tsunamis. Restoration of riverine wetlands could help lower the delivery of nutrients to coastal waters, decreasing problems with hypoxia and preventing the loss of economic benefits from the harvest of shellfish and fin fish. In addition, land management practices that reduce nutrient pollution and sediment export from cropland would benefit both the aquatic systems within agricultural watersheds and the coastal environments downstream.

Water and Society

The human and cultural dimensions of our relationship with water are perhaps the most difficult to assess, describe, and quantify; yet our cultural, aesthetic, and spiritual relationships with water are among the most powerful forces spurring society to action. Connection to place, and often to places that are characterized by the presence of water, has been recognized as an important aspect of the development of a conservation ethic. Water is an integral part of religious ceremonies in many cultures, and specific water bodies (such as the Ganges River for Hindus) are sites of holy pilgrimage.

Reliable Information on Water Use

Current efforts toward global assessments of the condition and trends of freshwater ecosystems worldwide are hampered by the lack of standardized, comprehensive data collection and by the transboundary nature of many of the world's

watersheds and river basins. Hydrologic stations around the world have been declining over the past three decades, and some important data (such as the location of small dams 15 meters in height or less) have not been collected. In the United States, annual threats to the budget of federal agencies charged with monitoring stream flow and water quality (i.e., the USGS and the U.S. Environmental Protection Agency [EPA]) have affected water-monitoring programs such as EPA's Index of Watershed Indicators (IWI) program (26% of U.S. watersheds have insufficient data for classification with this index) and the USGS National Water-Quality Assessment (NAWQA) program. In addition, funding for the 50 state Water Resources Research Institutes has been threatened annually throughout the early part of this millennium. Scientists who rely on such programs for critical data on the nation's water resources must expend substantial energy each year in attempting to reinstate funding for these programs. Consistent underfunding of NAWQA has required the USGS to prioritize watersheds for monitoring, shifting focus from region to region every few years rather than maintaining long-term, continuous monitoring programs in the 60 basins identified as a representative sample of watersheds nationwide.

The collection of comprehensive, basic hydrological and geochemical data worldwide would significantly enhance the ability to monitor the status and condition of the world's freshwater resources and to anticipate and address threats to freshwater ecosystems. To manage water resources effectively, water scientists need to develop a global database that will allow the monitoring of precipitation, runoff, stream discharge, withdrawals for various uses, and water quality data collected, using the standard methodology. Key water quality variables that need to be measured include sediment and dissolved organic carbon, temperature, nutrients (especially compounds containing nitrogen and phosphorus), bacteria, and the occurrence and abundance of organisms that cause waterborne diseases.

Data concerning groundwater withdrawals are even more difficult to obtain than data on surface water withdrawals, compounding the difficulty in understanding current uses or forecasting the sustainability of the world's water supplies. The WRI

recommends the compilation of a global data set on groundwater resources (including their distribution, capacity, and use) and has encouraged national governments to establish water-quality-monitoring programs that combine chemical and biological measures of water quality for both surface water and groundwater.

Finally, information concerning the value of ecosystem services provided by freshwater ecosystems, including wetlands, lakes, rivers, and streams, should be placed in the hands of decision makers. Decision makers at many levels are often uninformed concerning the value of the many ecosystem services provided by freshwater ecosystems and the benefits these systems provide to people. As a result, their decisions are seldom informed by even semiquantitative estimates of the economic value of both the marketed and the nonmarketed services provided by freshwater ecosystems, leading to an undervaluing of those services in decision making.

Conclusion

Freshwater is one of the world's most precious as well as most threatened resources. Conservation of existing freshwater resources, protection of surface and groundwater from pollution and overuse, and distribution of clean water for drinking and household use to regions where water is scarce will be among the greatest challenges to the national governments of the world in the next century, as population increases and clean water becomes increasingly scarce. Strengthening and informing the institutions responsible for water governance will also be critically important in ensuring that the water needs of the future are met.

in aquatic ecosystems. Pathogens serving as typical microbiological pollutants cause many illnesses ranging from typhoid and dysentery to minor respiratory and skin diseases. Chemical pollutants are poisonous to aquatic life, birds, animals, and people. Excess inputs of nutrients from agricultural management lead to eutrophication—the excessive growth of algae, periphyton, and weeds, which can deplete dissolved oxygen to the detriment of fish, reduce potability, and preclude recreational uses of water. Suspended sediment threatens aquatic ecosystems directly and indirectly. Reduction of light penetration due to the presence of suspended sediment directly reduces photosynthesis. In addition, sediment smothers bottom-dwelling organisms and clogs fish gills, prevents successful development of fish eggs and larvae, and modifies fish movement and migration. Indirectly, suspended sediment serves as a carrier for the nutrients, metals, and organic biocides that adsorb to the sediment.

Because of the complex interaction between groundwater and surface water, groundwater pollution, sometimes referred to as groundwater contamination, is not included here. Surface water pollution is generally classified by sources into point and nonpoint source pollutions. Point source pollution refers to the process by which harmful substances enter a waterway through a discrete conveyance, such as a pipe or a ditch. Examples of point sources include discharges from a sewage treatment plant or a factory, or a tributary that transports pollutant loads into the main stream. Nonpoint source pollution refers to diffuse contamination that does not originate from a single discrete source. It is often a cumulative effect of small amounts of contaminants gathered from a large area. Nutrient runoff in storm water from “sheet flow” over an agricultural field or metals and hydrocarbons from an area with highly impervious surfaces and vehicular traffic are sometimes cited as examples of nonpoint source pollution. Different types of nonpoint source pollutants derive from different types of sources. Suspended sediment is largely originated from cultivated agricultural lands, deforested areas, urban construction sites, dirt roads, and even eroded channel banks. Phosphorus inputs mainly come from fertilizer applied to agricultural soils and

WATER POLLUTION

Water pollution occurs when harmful materials are introduced into the lakes, rivers, oceans, and groundwater. These harmful materials are referred to as pollutants. There are a variety of pollutants ranging from biological (e.g., bacteria and viruses) to chemical (e.g., metals, solvents, pesticides, and floating detergents and oils) forms, and from nutrients (e.g., phosphorus and nitrogen) to suspended sediment. They cause diverse problems

manure supplied from concentrated livestock operations. Although, part of it (about 30% of the total input in the United States and Europe) can be sequestered by crops, the majority of applied phosphorus remains in the upper 10 centimeters of soils in the agricultural fields or exports to surface waters by erosion or leaching. In the United States and Europe, only 18% of the nitrogen input in fertilizer is removed from farms in produce. The surplus of nitrogen may accumulate in soils, erode, or leach to surface water and groundwater. Some may enter the atmosphere through volatilization of NH_3 (ammonia) and microbial generation of N_2O (nitrous oxide). Much of the nitrogen volatilized to the atmosphere is subsequently redeposited on land or water and eventually returns to aquatic ecosystems.

The degree of water pollution can be quantified by water quality, the physical, chemical, and biological characteristics of water in relationship to a set of standards. The most commonly used criterion for measuring water quality is the total maximum daily load (TMDL), which is a calculation of the maximum amount of a pollutant type that a water body can receive and still safely meet the water quality standards. The TMDL is the sum of the individual waste load allocations (WLAs) for point sources, load allocations (LAs) for nonpoint sources and natural background, and a margin of safety (MOS)—that is,

$$\text{TMDL} = \sum \text{WLA} + \sum \text{LA} + \text{MOS}.$$

According to the U.S. Clean Water Act Section 303 implemented in 1972, each state is required to identify and list the impaired water bodies based on its TMDL standards.

Pollutant loads from point sources such as municipal sewage treatment plants tend to be continuous, with little variability over time. Often they can be monitored by measuring water discharge and pollutant concentrations periodically at a single place. Consequently, point sources are relatively simple to measure and regulate and can often be controlled by treatment at the sources. The primary focus of legislation and efforts to curb water pollution for the past several decades was on point sources. However, it is well-known that nonpoint sources are now the

dominant inputs of both sediment and nutrient pollutants in most U.S. surface waters. Therefore, greater attention has been placed on the contributions from nonpoint sources, especially in rapidly urbanizing or developing areas. Nonpoint source pollutants often derive from extensive areas of land and are transported via overland and underground or through the atmosphere to receiving waters. Therefore, estimation of nonpoint source pollution loads is much more difficult because the diffusive nature of the sources means that the affected area is extensive and hard to identify due to the complicated processes of pollutant movement.

Physical processes relevant to nonpoint source pollution are easier to understand from the perspective of the watershed, which refers to the area of land where all the water that is under it or drains off it goes into the same place, termed the *outlet*. A watershed is a basic geomorphic unit that can be appropriately divided into two components: hillslope lands and the stream network connected to them. Nonpoint sources of pollution are typically located in hillslope areas, but the associated pollutants can affect a large portion of the downstream area by their movement with surface and subsurface flow. The processes of pollutant transport may be described as solid particulate transport and dissolved substance movement, respectively. The former includes suspended sediment and particulate phosphorus and other compounds that can be absorbed on sediment, whereas the latter mainly contains dissolved phosphorus and nitrogen. Suspended sediment is transported by surface runoff. A large proportion of phosphorus is transported with suspended sediment. Therefore, the concentration of phosphorus in water bodies is normally positively related to that of suspended sediment if management practices for phosphorus are not implemented. Nitrogen is primarily transported in dissolved form through surface runoff and subsurface or groundwater through infiltration and leaching.

The processes of pollutant transport are complex. Soils eroded from nonpoint sources such as agricultural fields and construction sites in hillslope areas of a watershed are transported by surface runoff due to rainfall or snowmelt in the form of rill or interrill flow (collectively termed *overland flow*) into the connected branches of the stream

Figure 1 A sediment-rating curve

Source: Author.

network. Part of the transported suspended sediment may be deposited in the stream bed and resuspended later. Therefore, the processes of suspended sediment transport are controlled by the intensity and duration of rainfall or snowmelt events, hillslope topography, land use and land cover, and in-channel hydraulic dynamics. These processes typically vary with both space and time.

Suspended sediment transport has been extensively studied for decades. Usually, suspended

sediment load Q_s is determined by establishing a sediment-rating curve (SRC) (Figure 1), which is a mathematical relationship between Q_s (or sediment concentration C) and Q

$$M = aQ^b,$$

where M is either Q_s or C , and a and b are rating curve parameters determined by regression analysis using data obtained via in situ sediment

sampling. Different values of a and b may be caused by factors such as different rainfall events or different extents of new sediment sources. The SRC method significantly reduces the sampling number required for estimating Q_s , compared with the traditional sampling method. It has been widely used to determine Q_s for a stream reach or an entire watershed for a single hydrological event, a year, or more than a decade. However, many watersheds do not have a functional relationship between the two variables, suggesting that Q may not be the only independent variable that controls Q_s . This is mainly because sediment transport is essentially not at capacity. Consequently, Q only reflects the available hydraulic capacity of transporting sediment. The actual in-channel sediment load can also be limited by sediment supply, which is related to many other environmental variables, such as topographic conditions, soil types, land use, and land cover. In these watersheds, if data for a hydrological cycle (e.g., a rainfall event) are plotted in the diagram of C against Q , the peak value of C is not in phase with that of Q . Instead of following an SRC curve, the data form a loop termed a *hysteresis loop*. The dynamic link between nonpoint sources and in-channel sediment transport may be revealed by analyzing the orientation of the loop, termed *hysteresis analysis*. For example, a clockwise loop may indicate that the upstream channel is the main sediment source or sediment depletion occurs on a hillslope, whereas an anticlockwise loop may suggest that sediment is directly derived from hillslope agricultural lands or there exists an additional sediment source due to bank erosion or sediment supply from upstream tributaries (see Figure 2).

The dynamics of phosphorus and nitrogen transport during a single hydrological event may be characterized by both the SCR method and the hysteresis analysis. The latter can be typically associated with the method of establishing a pollutogram, expressed as

$$F = X^\beta,$$

where F and X are the cumulative percentage of the total amount of a pollutant and water for a single hydrological event, respectively, and β is the coefficient, whose values of greater or less

than 1 indicate that the pollutant arrived predominantly toward the beginning or end of the event, respectively. The value of 1 for β signifies that the pollutant concentration is constant during the event.

In addition to temporal variation, pollutant transport also varies in space. The spatial distribution of pollutant loads has been conventionally characterized using various process-based watershed models, which use various mathematical equations to describe the hydrological, sediment, and chemical processes involved and automatically link the solutions of the equations among spatial elements in terms of physical principles such as mass balance and wave propagation. According to their different spatial arrangements, watershed models may be generally categorized as lumped and distributed models. In the former, such as the Dynamic Watershed Simulation Model and the Soil and Water Assessment Tool, a watershed is divided into limited, relatively coarser areas assuming that variations of various physical processes controlling pollutant transport within each area are negligible. In the latter, such as the Annualized Agricultural Nonpoint Source Pollution model and the Better Assessment Science Integrating Point and Nonpoint Sources model, however, a watershed is dissected by a grid with regular sizes, and each cell has values representing its physiographic conditions. The lumped models are relatively simple and easy to use, but they may inappropriately ignore the process variations within the spatial elements used in the models. The distributed models can accurately characterize the processes involved in pollutant transport at very small spatial scales, but often their input files are very complicated, and some of the required input parameters are not known and have to be artificially created. With respect to predicting pollutant load for the entire watershed, both types of models behave similarly.

WATERSHED MANAGEMENT

Water management is a very broad term that pertains to the design and deployment of planning approaches to access and supply water. The term encompasses the planning and provision of water quantity (adequate volume of supply), water quality (safety of source), and also flood protection. Originally the term implied provision of water only for people, but more recently it has begun to

incorporate adequate supply and quality for the natural environment—namely, wildlife and its habitat. Water is essential for all life, and an increasing number of locations encounter either water quantity or quality concerns. This entry discusses water quantity, the philosophies of managing water quantity in the United States, water quality, flood protection, and water management through good governance.

While more of Earth's surface is covered by water (approximately 70%) than land, because of the vast size of the oceans, the majority of the planet's water is saltwater (97.5%). Of the 2.5% of water that is *freshwater*, approximately 70% is frozen in the Arctic and the Antarctic or is effectively inaccessible to humans as soil moisture or deep groundwater. Of the world's total water, only about 0.007% is freshwater available for human use. Freshwater is a globally scarce resource, and it also has a highly variable distribution depending on location and climate. Water management is a core topic of geography as it links both natural systems and human action. A watershed is geographically defined in hydrology as consisting of all areas that drain to a common waterway. While watershed-based management is the logical approach to benefit hydrology, watersheds often transcend political boundaries, making watershed management more challenging.

Water Quantity

Provision of an adequate volume of freshwater supply, or water quantity, is a primary concern of hydrologists, planners, and other individuals responsible for water management. While freshwater is globally scarce, its distribution is highly variable, which means that different locations encounter distinctive challenges to provide freshwater supply for human and industrial use. For example, arid regions in the southwestern United States have severe water shortages, while water-rich areas along the Great Lakes (the United States and Canada) have plentiful supply.

In general, management of water quantity is best approached at the drainage basin or watershed scale, which is the extent of land (the catchment area) that channels snowmelt and rain drainage into a waterway. However, water, particularly

lakes and rivers, has been traditionally used as a convenient geographic feature of the landscape to divide land into different political boundaries. This means that many watersheds cross political boundaries at different scales. Some examples of transboundary rivers include the Colorado River, which forms part of the boundary of Arizona with Nevada and California, and the Ohio River, which forms the southern boundary of Ohio, Indiana, and Illinois and the northern boundary of West Virginia and Kentucky. Some national boundaries are also formed by rivers, such as the Jordan River, which flows along Syria, Israel, Palestine, and Jordan, or by lakes, such as the Caspian Sea, which borders Azerbaijan, Iran, Kazakhstan, Russia, and Turkmenistan.

Even if water is not the actual boundary, water also flows through different political boundaries, making the management of water politically challenging. Consider, for example, the Tigris and the Euphrates rivers, which have headwaters in Turkey and flow through Syria and then into Iraq. Depending on their position within the watershed, nations often adopt different views as to how water management should be approached. Turkey views the Tigris and Euphrates system, which is sourced in that country, as a resource that it has the right to contain and has built the Ataturk dam and other smaller dams to manage the flow of water from Turkey into Syria. Downstream, Syria and Iraq argue that they have a right to the water that traditionally flowed through the rivers' water course and contest Turkey's right to restrict the rivers' flow north of their borders. In a world with a growing population and an increasing demand for limited water, water management is a real source of conflict, particularly where watersheds cross political boundaries. Indeed, several books have explored the issue of wars over access to water. Even within nations, there can be conflict over how water should be allocated. One recent example in the United States is the dispute between Virginia and Maryland about the right of a growing suburban county in Virginia to access additional water from the Potomac River. That this dispute had to be settled by the U.S. Supreme Court in 2003 demonstrates the intensity of conflict surrounding access to water.

Philosophies of Managing Water Quantity in the United States

Within the United States, water allocation is within the purview of individual states, and there are two philosophies about how water allocation should be managed. The Mississippi River geographically divides the two different philosophies, with the *right-to-use* riparian doctrine to the east and the *prior appropriation* doctrine to the west. The demarcation of these is linked to both the biogeography of the regions and the historical uses of the water.

Right to Use

The right-to-use doctrine means that property owners along rivers and lakes have a right to reasonable use of the water as it flows past their property. Use is considered reasonable if the quantity and quality of flow are not diminished, preventing other riparian users from making reasonable use of the water. The right-to-use doctrine is used in states with moister climates and more plentiful water sources, though as with the example of Virginia and Maryland above, even locations that traditionally had larger volumes of water are encountering water management conflict with the rising population and increased use of water resources. Increasingly, the right to use depends on governmental regulation to monitor the reasonableness of use. This regulated riparian system is administered by state agencies that apply the principles of reasonable use to issue permits for the use of or discharge into water.

Prior Appropriation

Prior appropriation became the method for water allocation in the western states because of their drier climate. Historically in the west, fewer people sought the rights to use water in association with mining claims and, later, for agricultural irrigation. With the higher annual variability in rainfall in the region, there was greater uncertainty about availability of water. Moreover, in the western states, where water is limited, limiting the use of water to only adjacent landowners would also limit the number

of settlements because nonriparian lands would have significantly diminished productivity. Hence, unlike the right-to-use doctrine, the prior appropriation doctrine separates water rights from land ownership. The principle of the prior appropriation doctrine is commonly explained as “first in time, first in right,” because it is a system where the earliest water users have rights to water that take precedence over subsequent claims. Through the prior appropriation doctrine, water rights entail the diversion of water from its source for a beneficial use. If appropriated water is no longer put to beneficial use, that right is lost as the right passes to the next user with a claim; this “use it or lose it” attribute of the prior appropriation system is not conducive to water conservation by users with early rights.

The growing population of the western states, high rainfall variability, and increasing demand for water mean that in years of low rainfall some rivers would effectively run dry. For example, the transboundary Colorado River, whose allocation was determined in the years following particularly high rainfall, has been so depleted that only a trickle enters Mexico, and in some years, the river no longer consistently reaches the sea, with devastating effects on wildlife and habitats in former wetlands and coastal areas.

Minimum Flows and Levels

The potential for devastation of the environment through overappropriation of water, particularly in low-rainfall years, in the 1990s led to an effort to devise a system to protect the environment, working in concert with the prior appropriation doctrine, in the watersheds of the western states. The western states now have instituted laws that ensure *minimum flows and levels* within watercourses to provide for the needs of habitat and wildlife. Rising demands for water in the eastern states under the right-to-use doctrine have also led to the formulation of water management regulations to protect minimum flows and levels for wildlife. One example is within the South Florida Water Management District. Here, the water management system has been significantly modified to incorporate

the needs of wildlife and its habitat for water of adequate quantity and quality.

Water Quality

While conflicts surrounding water allocation relate to the ability of competing interests to access sufficient quantities of water, water quality issues largely pertain to concerns over the deterioration of water as a result of pollutants entering waterways. Water quality issues tend to manifest more in downstream portions of rivers, which experience accumulation of pollution from upstream. Two types of pollution can occur: (1) from *point sources*, that is, single identifiable sources such as factory pipes discharging effluent into a river, and (2) from *nonpoint sources*, which consist of many diffuse sources, including water runoff moving over or through the

ground transporting urban pollutants, fertilizers, contaminated sediments, or biological waste.

Point source pollution is easier to regulate than nonpoint source pollution. One of the key challenges of managing nonpoint source pollution is that while the individual activities may fall within environmental safety guidelines, the cumulative effect in the watershed is the creation of unsafe levels of pollution. While, at an additional expense, water can be treated to improve water quality before distribution for human consumption, poor water quality also has a deleterious effect on the natural environment. For example, in the Florida Everglades, elevated levels of naturally occurring phosphorus have resulted in a shift from natural to invasive vegetation, resulting in a negative effect on wildlife, including endangered species.

Flood Protection

Flood protection is a high-profile aspect of water management. Flood protection largely entails protecting homes, roads, and other aspects of the built environment from inundation during high-water events. In many locations, flooding is part of the natural cycle of a watershed. For example, until the Aswan Dam was constructed, the Nile River annually overflowed its banks, depositing soil sediments and making the area fertile for agriculture. Throughout the world, many dams and levees have been built in an attempt to prevent flooding of property. While these water management structures offer some stabilization of water levels and flood protection, they may be unable to provide protection from extreme high-water events and also may have deleterious effects on the environment.

In addition to protection from flooding of rivers, flood protection encompasses protection of coastal areas from hurricanes, typhoons, and storm surges. Recent events have demonstrated the devastating effects of inadequate coastal defenses, such as the 2004 tsunami and the breaking of the New Orleans levees by Hurricane Katrina in 2005. Beyond surface inundation, flood protection is also important for preventing saltwater intrusion of freshwater aquifers, which once contaminated may take many years to be usable again for human's freshwater needs.

Managing Water Through Good Governance

Water management concerns in the 19th and 20th centuries were understood as technical issues to be solved by hydrologists and engineers. Since the end of the 20th century, there has been a shift toward understanding water management concerns not only as engineering challenges but also as highly contested, often politicized, issues that require the engagement of wider stakeholders toward designing sustainable and equitable water management strategies. Good governance of watershed-based management requires the inclusion of wider-ranging nongovernmental interests in shaping water management policy for a given watershed, which

is important in light of increasing demands for limited water. One example where water management practices were significantly modified through the integration of wider stakeholder groups in a watershed-scale planning process was in South Florida. Through the involvement of competing stakeholders, a common vision emerged for improving water management. This perspective included a shift in focus from primarily water supply and flood protection to provision for the environment toward securing the long-term sustainability of the water supply to meet an anticipated growth in both human demands and environmental needs.

WATERSHED YIELD

The ebb and flow of sediment movement in a watershed is spatially and temporally complex and difficult to quantify. However, attempting to quantify and understand sediment dynamics in a watershed is important for the successful management of aquatic and terrestrial ecology and

the associated health of the watershed. Soil erosion is a worldwide problem that has degraded small and large watersheds. Estimating the sediment yield of a watershed helps resource managers understand the amount of soil erosion that exists and how much sediment is stored in the watershed. Within the fluvial hierarchy, watersheds provide a spatial framework by which the physical and environmental metrics influencing sediment movement can be evaluated. A watershed is defined as the contributing area of land that captures and drains precipitation to an outlet point, which does not have to be a stream or lake confluence. Rather, the outlet can be a point on a stream reach, and the contributing area of the watershed would be delineated from the predefined point.

Sediment yield in a watershed is quantified using the amount of sediment passing a point in the watershed per some unit of volume per time (i.e., cubic meters per kilometer per year) or mass per time (kilograms per square meter per year). Sediment yield can be estimated by coring reservoirs and lakes, performing suspended sediment sampling at the outlet, direct site observation and calculation of erosion, and computer modeling. Reservoirs and lakes act as sediment traps and through coring or bathymetric surveys can provide an insight into temporal and spatial changes of sediment routing through the watershed. Suspended sediment is measured at the outlet and plotted against discharge. A rating curve can be established if the duration of sampling spans multiple high- and low-discharge events. The source of suspended sediment (mostly silt and clay) is mainly from surface and subsurface erosion, which includes roads, culverts, tile lines, rills, gullies, overland flow, and stream banks. One of the concerns of only measuring suspended sediment is that bed load transport is not accounted for. However, bed load normally comprises a small amount of the sediment transport in large river systems. Direct site observations are difficult and time-consuming. In turn, soil erosion models have become a popular means of establishing the erosion estimates. These include, but are not limited to, the universal soil loss equation, revised universal soil loss equation, water erosion prediction project (WEPP) model, and geographic information systems (GIS).

Sediment is mobilized and transported in a watershed by physical and chemical weathering and erosion. Only a small portion of the sediment eroded in a watershed is quantified as the sediment yield of the watershed. This is because sediment is deposited and stored throughout the watershed. Temporary and permanent storage exists on the bed of the channel, bars, floodplains, wetlands, impoundments, and hillslopes. Watersheds of contrasting size route sediment differently. Watersheds draining a small area will generally have sediment yields greater than watersheds draining a larger area. Where relief and hillslope gradient are higher, sediment has a greater opportunity to reach the stream. Watersheds draining a larger area have streams that parallel floodplains and terraces, which store flood deposits and hillslope-generated sediments.

Besides watershed size, variables that influence sediment yield include climate and precipitation, vegetation, soils, topography, and land use. Rainfall has the ability to intensify erosion, especially on high-gradient slopes with sparse vegetation. Vegetation captures rainfall, and through the process of stem flow and the interception of falling droplets, infiltration occurs and rain splash erosion is decreased. In addition, roots of the vegetation (on hillslopes and floodplains) hold the soil in place, which increases cohesion and decreases surface erosion. Coarse-textured soils with low infiltration capacity, hydrophobic soils, and soils with low organic matter or weak structure tend to be the most susceptible to erosion. Generally, particle size decreases downstream, and because larger streams are inset into their own deposits, bank cohesion increases while sediment yield decreases. However, it is important to recognize that this oversimplified fining hypothesis is spatially complex. Under the influence of gravity, slopes with higher gradient and longer slope length cause increased soil erosion. Changes in land use affect the sediment yield in a watershed. Anthropogenic changes, including mining, deforestation, urbanization, fire, and agriculture, have altered sediment yield worldwide.

Researchers have attempted to portray sediment yield in a regional context, but high spatial variability has limited the results. When sediment yield is plotted as a function of precipitation, three sediment yield peaks exist at (1) ~450 mm (millimeters; continental semiarid climate), (2) 1,250

to 1,350 mm (Mediterranean climate), and (3) >2,500 mm (tropical monsoon climate). The peak at ~450 mm corresponds to a transitional zone between desert shrub vegetation and grasslands. Precipitation slightly greater than ~500 mm is associated with grasslands and forests, with a decrease in the erosion potential. Sediment yield peaks at 1,250 to 1,350 mm and >2,500 mm are associated with seasonal precipitation amounts. Concerns about relating sediment yield to precipitation are that (a) seasonal precipitation affects the vegetation, which determines the erosion potential, and (b) anthropogenic alteration to the environment will mask the role of precipitation. Sediment yield should be determined on a watershed-by-watershed basis because of the inherent variability that exists in sediment transport and storage throughout the watershed.

WATER SUPPLY SITING AND MANAGEMENT

Water is a critical resource for the health of ecosystems and the reproduction of society. Water siting refers to the process of transformation of this basic component of the biosphere into a resource able to satisfy human needs. Siting includes, therefore, both the places where water is captured for human activities and the technologies and institutional arrangements that make this transformation possible. Water management refers to the institutional, legal, and technological arrangements by which water is allocated temporally and spatially to the different users (agriculture, industry, urban, environmental flows).

Surface water and groundwater are the two main conventional sources of freshwater, and their use entails different technologies of capture and also different institutions to regulate its use. Surface water of rivers and lakes can be directly captured from the source by means of ditches, especially for agricultural use. However, for thousands of years, dams, reservoirs, and channels have been developed to guarantee water availability where and when needed. Interbasin water transfers are justified on the ground that they contribute to redress the balance between “surplus” and “deficit” basins. Dams, reservoirs, and water transfers are important human interventions to mobilize and transform nature and have important consequences on the environment and society. While these interventions allow population and crop growth where water is scarce, they also modify the physical environment and affect the living condition of local populations and environments.

Aquifers are underground geological formations formed by layers of porous and permeable materials containing water. By means of wells or pumps, water can be brought to the surface. In this case, the use and consumption of water tends to be more local. Overextraction of water from aquifers can cause depletion and pollution, often irreversibly damaging the source.

Other nonconventional sources of water supply may be also relevant in some contexts. Desalination technologies involve several methods to

Aerial view of the spillway at Broken Bow Dam on Broken Bow Reservoir on the Mountain Fork River in McCurtain County, Oklahoma. This photograph shows only the spillway. turn seawater or brackish water into freshwater. Currently, the most efficient of such methods is called reverse osmosis. However, large amounts of energy are consumed in the process, with subsequent emissions of carbon dioxide (if the primary energy sources are fossil fuels). In turn, this process is reflected in the economic costs and subsequently limits such technology to urban (including tourist related) and industrial uses in the developed world.

Water harvesting is another technology traditionally practiced in the developing countries. It consists of the capture and storage of rainwater and has the advantage of not requiring a large infrastructure. Its usefulness at the local scale makes it an interesting resource that is being rediscovered in Western societies. Equally, the treatment and reutilization of wastewater (gray water) by means of small-scale or centralized utilities can

be a resource for agriculture, industry, and even household outdoor uses. This practice is common in California.

Water management requires the existence of a series of formal and informal institutions, practices, and regulations that determine how water is to be allocated across space and time among different users. Agriculture accounts for most of the water consumption worldwide. However, urban water consumption is dramatically increasing due to the processes of urbanization of rural land in the developing world and the increase of water consumption in Western urban areas because of changes in urban patterns and the widespread use of water-consuming appliances. Tourism also accounts for an important share of urban water consumption in some regions of the world, especially in the coastal temperate areas. Eventually, industry

could be a heavy and intensive user of water depending on the activity, and it especially affects water quality.

The special characteristics of water differentiate it from other raw materials such as oil, minerals, or food in transportation at the international level. Water sources tend to be acquired locally or regionally. Although water use is geographically bounded to place, international trade of commodities, from garments to vegetables to computers, implies a very significant flow of “virtual water,” that is, the water that has been used locally to produce each item. Increasingly, trade strategies are considered by water-stressed countries to alleviate water scarcity.

During the 20th century, engineering perspectives on water supply have reigned supreme, and policymakers have tended to centralize and increase supply by building new infrastructure to capture water. Although much of this philosophy still persists, there is an ongoing transition from a supply-side approach to water resources toward demand management, which tends to make the most of available resources while downsizing the scale of the infrastructure of supply. Demand-side management includes both economic and noneconomic tools, such as educational campaigns, restrictions, and so on. Price mechanisms are the main instruments for regulating demand and promoting the efficient use of resources. Efficiency in the management and use of water is deemed essential. Institutional changes become materialized in new water legislation that—for example, in Europe—tends to establish the river basin as the unit of policy action and integrated water resources management and for incorporating environmental costs into the price of water for full cost recovery of water supply. Water markets represent an important institutional arrangement to allocate water to the highest economic value (e.g., in Chile, Australia, South Africa, and the Western United States).

To sum up, water siting and management comprise both supply- and demand-side management strategies, encompassing a series of technological and political arrangements. As long as climate variations enhance water stress in some parts of the world, technology, productive activities, and urbanization may either alleviate this

situation or contribute further to the social scarcity of water.

WATTS, MICHAEL (1951–)

Michael J. Watts is a Marxist geographer specializing in political ecology and economic geography. Born in England, Watts has published more than 200 scholarly articles, books, and essays that have appeared in leading journals in geography and anthropology. His work focuses on the politics of oil, agrarian political economy, and development. Much of that work is based on field research in Nigeria and West Africa and related work in India, Vietnam, and the United

States. He is the Class of 1963 Professor of Geography at the University of California, Berkeley, where he has taught since 1979. Watts's scholarly work combines his commitments to social change with his formidable intellect, yielding a wide-ranging body of work whose influence extends far beyond geography.

Watts is widely regarded as a founding figure in the field of political ecology for his initial research on the politics of famine in Nigeria during the 1970s. Drawing from his training in cultural ecology and anthropology at the University of Michigan under Roy Rappaport, Bernard Nietschmann, Eric Wolf, and Michael Taussig, Watts brought Marxist political economy to bear on questions of nature and society. He argued that famines were crises of distribution that laid bare the structural inequalities of capitalist markets as means of distribution, challenging the prevailing neo-Malthusian accounts of famine as instances of scarcity created by the demands placed by a growing population on natural resources. Watts's arguments also challenged Nobel laureate Amartya Sen's critical explanation of famine as an outcome of the social curtailment of freedom.

One of the last students to receive a doctorate in geography at the University of Michigan, Watts's approach contrasted sharply with the lingering influences of Carl Sauer's "Berkeley School" of geography that he encountered as a new professor. At Berkeley, Watts developed his approach to political ecology through engagement with questions of culture, power, and political economy through participation in critical efforts to rethink Marxist political economy. In particular, Watts drew on the works of Raymond Williams and E. P. Thompson to address the importance of culture to questions of nature, resource struggles, and society, engaging with poststructuralism and the cultural turn in the social sciences. Together with Alan Pred, he developed a critical approach to studying capitalism in terms of its historically and geographically specific patterns of accumulation and forms of resistance. Watts continues to develop these themes through research on the politics of oil in the Niger Delta, bringing Foucaultian-inspired analytics to bear on questions of governance and natural resources.

A geographer unburdened by the disciplinary bounds of the field, Watts has helped influence a range of research as a collaborator, colleague, and advisor. At Berkeley, Watts served as director for the Institute for International Studies from 1994 to 2004, founding a series of seminars and colloquia that shaped a generation of scholarship. In particular, the Berkeley Workshop on Environmental Politics, which he cofounded with Nancy Peluso and Donald Moore, has become a critical locale for debates on environment, cultural politics, and political economy. He has also worked with Gillian Hart to build Berkeley's programs in development studies and African studies. He has directed more than 60 doctoral dissertations, and many of his students are now prominent scholars in geography. He is also one of the more highly regarded lecturers on the Berkeley campus. Watts has received numerous awards and accolades during his career, including a Guggenheim fellowship in 2003 for his work on oil in Nigeria. He delivered the first talk in the Hettner Lecture series at the University of Heidelberg in 1999.

WAYFINDING

Wayfinding is the cognitive-conceptual process of finding and planning a route from an origin to a destination through a known, partially known, or

unknown environment. Travel from an origin to a destination is a fundamental human activity that nearly everyone completes on a daily basis. The centrality of wayfinding to humans is made evident by the expanding knowledge domain specific to wayfinding and related concepts as well as the booming, multimillion-dollar industry providing services and support for wayfinding and navigation technologies.

Wayfinding should be distinguished from locomotion (movement) and navigation. Wayfinding is the cognitive-conceptual aspect of route finding and planning, locomotion refers to the actual physical movement of a cognitive agent in an environment, and navigation is a stylized form of wayfinding that typically includes guiding a vehicle such as a ship or an aircraft. Wayfinding's cognitive-conceptual nature is stressed as it synthesizes complex cognitive processes (e.g., landmark recognition, route retracing, route planning, route selection, path integration) with conceptual primitives of spatial knowledge (location, direction, distance, connectivity, and spatiotemporal sequence).

The basis for wayfinding is knowledge about one's environment, or if knowledge (internal/mental or external) is not available, the administration of a wayfinding strategy to uncover such knowledge. In addition to the primitives of spatial knowledge mentioned above, successful wayfinding also requires knowledge about landmarks (salient objects located in an environment), knowledge about routes (how landmarks and other salient locations are connected), and survey knowledge (how landmarks and routes are spatially arranged).

Research on landmarks has undergone a renaissance in recent years because of the increased availability of navigation devices and improved analysis functions for identifying landmarks for use in navigation services. Mimicking the extensive human emphasis on landmarks when wayfinding, several technological developments now allow for the automatic identification and selection of landmarks in databases, three-dimensional city models, and the Internet. Across all proposed landmark taxonomies, two orthogonal approaches can be distinguished: (1) reference to the landmarks themselves, identifying three kinds of landmark salience (visual, semantic, and structural), and (2) focus on the geometric conceptualization

Figure 1 The interaction among wayfinder, environment, and representations of the environment

Source: Author.

of the landmark when used in wayfinding and navigation, indentifying three geometric dimensions (pointlike, linear, or area-like).

The first step in every wayfinding activity is to determine one's location in the environment. This location information, from a cognitive point of view, is not the exact coordinate pair at which a wayfinder is located but an alignment of the wayfinder's mental representation of the environment and the information the wayfinder is accessing either directly (through perceiving his or her surroundings) or indirectly (e.g., through a map). Figure 1 shows this triangular relationship schematically with relations among the wayfinder, the environment, and an external knowledge source such as a map.

Some wayfinding strategies are employed when one's current location or possible wayfinding routes are partially or completely unknown. In these cases, the term *wayfinding* is used in its most literal sense: to find one's way. Other wayfinding strategies are specific to route choice behavior; that is, from a given set of known alternatives a specific route is chosen. Examples are choosing the shortest or longest route segment first or choosing the route segments with the smallest deviating angle from the destination.

Most wayfinding activities take place along constraining artifacts such as street or public

transportation networks. Even most natural environments offer superimposed artificial structures such as trails. It is of crucial importance to understand the influences that specific environments have on wayfinding and on wayfinding success. This point becomes particularly apparent when the environment, either cultural (e.g., a city layout of streets and buildings) or natural (e.g., mountain ranges), is misaligned from our mental preconceptions. Examples include the northwest to southeast orientation of the mountains located outside Santa Barbara, California, or the southwest to northeast isthmus on which Madison, Wisconsin, is built. The naming of features within these landscapes, based on the traditional gridded city block convention of the United States, often contrasts with the true characteristics of the feature.

Other examples that stress the importance of the environment on wayfinding become apparent when we look at different wayfinding strategies. How is wayfinding in street networks different from wayfinding in deserts? While in relatively unstructured environments, such as open oceans or deserts, information about one's location and especially direction (i.e., bearing) is of utmost importance, the constraining nature of structured environments deemphasizes these spatial primitives and places a greater emphasis on connectivity. For example, when wayfinders are moving through a road network, choices about where to turn are very limited and the actual turning angle is of secondary importance. The initial physical turn (e.g., at a highway interchange) may even be in a direction opposite the planned direction change.

The importance of understanding and using the knowledge that an environment offers is recognized in several research communities and is gaining particular importance for researchers interested in supporting wayfinding through cognitively ergonomic navigation devices. For example, an understanding of the environment can lead to a tremendous reduction in the amount of information that a wayfinder must remember during the process of wayfinding. If this inherent environmental knowledge can be formally characterized through a cognitively guided analysis of an environment, these principles of understanding and organizing an environment can be used to communicate environmental knowledge and/or help wayfinders better understand their surroundings.

Wayfinding, especially in large cities but also on a geographic scale, often takes place in a multimodal environment that offers various forms of transportation. Pedestrian walks are combined with public transportation, which in itself can be a combination of, for example, buses and subways. Taxicab rides to an airport are combined with indoor wayfinding in airport buildings, flying to another airport, and so forth. The challenges of multimodal wayfinding are manifold and often involve tasks such as temporal sequencing of events, switching between different signage systems (indoor vs. outdoor), and switching from constrained travels (e.g., a cab ride) to semistructured wayfinding in large airport spaces.

In summary, wayfinding is a cognitive process that synthesizes a variety of cognitive subprocesses and combines different kinds of spatial knowledge. Wayfinding and wayfinding strategies are deeply interwoven with the characteristics of an environment in which the wayfinding process takes place. Current developments in technology support wayfinding services by providing tailored, cognitively ergonomic information solutions. Wayfinding, as an everyday process, is central to a modern understanding of spatial cognition.

WEATHER AND CLIMATE CONTROLS

Climate, which consists of observations of meteorological parameters (i.e., weather) over a specified period of time, is shaped by many environmental factors. Although weather conditions at any particular time can be ephemeral and deviate from expectations, over a long period of time, certain characteristics are associated with any given location on Earth. The longer the period of record, the more likely that climate regimes will be identifiable with recognizable temperature and precipitation characteristics. This entry discusses seasonal changes in climate as well as major controls and localized controls on weather and climate.

Seasonal Changes in Climate

The seasons are among the most well-known environmental parameters that affect long-term climate and shorter periods of time associated with weather. Seasonal changes in climate for a given locale are imprinted on the daily lives of the biology in these locales, in everything from the smallest plants to the local human inhabitants. For example, anyone reading this passage may be able to picture the environmental conditions in their own hometown during each of the four astronomical seasons and may also imagine the likely climate conditions present during these seasons. These “memory maps” of climate changes due to the seasons can be found in anyone inhabiting a particular area for a long enough period; in fact, with enough living experience, nearly all biological life forms appear to incorporate temperature and/or moisture into their evolutionary adaptations, associated with particular sites on Earth.

It is important to note that the effect of seasons on weather and climate is solely due to changes in solar insolation (incoming sunlight) during the year, and this is reflected in the latitude of an individual location above or below the equator—all places along a given latitude will receive these changes in incoming solar energy. The general patterns of incoming energy are reflected in the seasonality, as discussed above. Although we have four seasons in the United States, other regions of the world do not have such distinct divisions in

yearly climate. For example, areas located within 23.5° of the equator have very minor changes in temperature throughout the year—these latitudes are commonly known as the tropics, as they lie between the maximum latitudinal extents of vertical solar declination. We refer to the annual range in temperatures in the tropics as very minor. In areas far to the north, such as Alaska and above the Arctic Circle, the annual range can be very great—these areas can receive lengthy periods of dim to no sunlight during winter, contrasted with lengthy periods of daylight through summer. Therefore, latitude plays a significant role in seasonal-scale climate trends. However, many other geographic parameters control the actual weather that occurs at any selected location, and these other controls on weather are the focus of this entry.

Major Controls on Weather and Climate

A general discussion of the controls on climate typically begins with the assessment of the thermal properties of land or soil versus those of water, typically referring to the oceans and their enormous heat storage capacity. Land absorbs the solar energy that is received during the day and rapidly heats up due to a low specific heat (a physical property referring to the energy a substance must absorb to raise the temperature of a 1-gram mass of water by 1°C). The reverse is also true: At night, when the sun is no longer providing incoming energy to the surface of Earth, the land cools down rapidly due to the same characteristic of low specific heat. The opposite is true of water, which has a very high specific heat. It takes a long time, therefore, for water to heat up and cool down. This is reflected in the long lag times between peak solar insolation and peak water temperatures. For example, if one were to visit one of the Great Lakes (such as Lake Huron or Superior) in May, one might find the water to be too cold to swim even on a 100°F day. However, visiting in August on a day with a maximum temperature of 85°F , one would likely experience water temperatures 10° to 15° higher. This is because even though the sun reaches its seasonal declination zenith on the summer solstice (June 21), it takes about another 30 days for this peak in incoming energy to translate into a peak in water temperatures. The end result in these differences

in specific heat between land and water is a greater range in temperatures in locations that are far removed from large bodies of water (called *continental climates*), with a smaller annual range of temperatures at locations located near such bodies of water due to the moderating effects of proximity to these features. Furthermore, these properties are reflected in the differences in climates between locations in the Northern Hemisphere versus those in the Southern Hemisphere. In general, Northern Hemisphere climates are more variable and have a higher annual temperature range than Southern Hemisphere climates. Once these more rapid swings in temperature over large land masses are considered, it is logical that the majority of severe weather events such as tornadoes, mesoscale convective complexes, and derechos occur in the Northern Hemisphere.

When one considers the differential heating between water and land, another factor must be considered—that of oceanic currents. Just because two cities at a given latitude are within a certain distance from an ocean does not imply that the weather at both places will be the same. In fact, ocean currents play a large role in the actual climatic conditions at these coastal locales. Typically, western coasts in the Northern Hemisphere are associated with cool currents, as colder water circulates toward the equator from the polar regions. This is reflected in the cool oceanic water off of the northwest coast of the United States—taking a dip in the waters off Seattle even in August can be quite a chilly experience. Surfers in California often have to wear wetsuits to prevent hypothermia, even as far south as Los Angeles or San Diego. The opposite is true of most east coast locales. For example, the water in Miami may be cool in winter, but it is still much warmer than water at the same latitude along the western coast of the North American continent. This is due to the Gulf Stream, an enormous current of warm water that travels up the eastern coastline of the United States before curving out into the Atlantic and flowing toward Europe. In fact, given the latitude of the United Kingdom and Northern Europe, winters would be much more severe if not for the modifying effects of the warm Gulf Stream flowing just offshore. Thus, in the Northern Hemisphere, cities near western coastal boundaries often experience cool marine climates, whereas

cities near eastern coastal boundaries often experience more continental climates, with a warming influence from northerly bound currents. These trends are reversed in the Southern Hemisphere.

A final observation on the differences in climate between two coastal cities located on opposite coasts includes an examination of the wind patterns at western versus eastern continental margins. For example, San Francisco, on the Pacific (western) coastline of the United States, experiences prevailing winds from the westerly direction, which drive the air situated above the cool California current ashore, producing cool sea breezes and late-afternoon advection fog. In contrast, Charleston, South Carolina, located on an eastern coastline, receives westerly prevailing winds also, but these flow from land toward the ocean (hence, a continental climate). Charleston's weather would be influenced by the warm oceanic current just offshore, resulting in milder wintertime temperatures. Therefore, the environment over which the prevailing wind travels helps control the climate patterns that subsequently occur, even at two coastal locations. These are collectively referred to as continental versus maritime climate controls.

Another major climate control is the altitude of any location. Since Earth's atmosphere is significantly denser at the surface than at increasing altitude, higher locations experience greater temperature ranges and are generally cooler than locations with lower altitudes. However, it is important to note an important caveat with the assumption that a linear decrease in temperature takes place with increasing elevation: The soil or material composing the majority of the exposed surface plays a large role in the true climatic conditions experienced at locations with high elevations. The concept of greater or lesser energy absorption based on differing reflectance properties of surface material is known as albedo. The end result, however, is that locations that are at similar elevations and similar latitudes may have different temperature ranges based on the underlying material that is exposed to sunlight. Darker rock or heavily built urban environments will be more likely to absorb and slowly release heat energy than environments containing lighter colored material or less built structure, which would tend to reflect more sunlight than the darker

material (higher albedo). This could result in the former possessing generally warmer temperatures and the latter exhibiting colder temperatures.

Localized Controls on Weather and Climate

Albedo can be associated with any feature covering Earth's surface. This includes not only snow, water, rock, vegetation, and human-made objects but also atmospheric features such as clouds. Therefore, excessively cloudy locations are likely to have lower daytime temperatures as much of the incoming sunlight is reflected out to space. One can often see this taking place when looking at large thunderstorms at a distance—the base of the cloud may appear dark, because most of the sunlight has been reflected off the top of the clouds, which may appear bright white. This relates to weather in that incoming sunlight that is not reflected is absorbed by Earth's surface, which slowly warms. Most of the heat energy in a location actually occurs from the ground up; therefore, the more sunlight absorbed, the higher the temperatures will be in general. Therefore, places with greater cloud cover are likely to have lower daytime high temperatures.

Water vapor in the atmosphere and in clouds actually acts as a greenhouse gas, absorbing heat energy and then reemitting it back toward Earth's surface. Therefore, water vapor and, in effect, cloud layers act as electric blankets—absorbing the energy released by Earth's surface at night and releasing it to the atmosphere. The end result is that while cloud cover lowers daytime high temperatures, it actually prevents nighttime temperatures from dropping very much. Very cloudy locations will show little variation in temperatures between night and day, assuming all other weather parameters are unchanged. One of the best examples of this would be the monsoon climate of southeast Asia, caused by a seasonal shift in wind direction. When the monsoon shifts to the rainy season, temperature variations between days and nights are miniscule.

Large-scale weather features, such as the subtropical high-pressure systems situated at about 30° north and south of the equator, the Inter-Tropical Convergence Zone, and climate teleconnections such as the El Niño–Southern Oscillation, can affect weather conditions on

climate timescales. As an example, the Bermuda High Pressure System, a strong anticyclone that commonly occurs during the Northern Hemisphere summer over the central Atlantic, can serve to both bring drought conditions to the southeastern United States and, at the same time, act as a steering mechanism for southerly-tracking hurricanes, funneling their tracks across Florida and into the Gulf of Mexico. The effects of El Niño, in particular, are known to vary geographically over relatively regional geographic scales.

Another relatively local control on weather conditions is orography, or the presence of mountain ranges. The orientation of the mountain range to the prevailing winds is essential in determining long-term climate patterns. North-south-oriented mountain ranges such as the Rocky Mountain Cordillera in the Northern Hemisphere or the Andes in the Southern Hemisphere are associated with a distinct climate boundary depending on which side of the mountain range experiences the prevailing winds. The side that experiences these winds will also experience rising air, which cools adiabatically, and a large amount of precipitation and cloudiness—this is known as the windward side of the mountain range. Descending air that has then crossed the mountain range sinks on the leeward side and warms adiabatically, essentially drying out. In these areas, deserts called rain shadows are commonly formed. Much of the arid southwestern United States is associated with this rain shadow phenomenon. Much of the effect of the monsoon in southeast Asia is associated with wind flow toward or away from the Himalayan mountain belt. It should be noted, however, that mountain ranges parallel to the prevailing wind direction have a lesser impact on local climates—the Alps of Western Europe, which are situated in a primarily east-west orientation, have much less of a windward-leeward relationship than the aforementioned North and South American Cordillera.

Other rarer and more localized weather controls include lake effect snows, lake breezes, mountain and valley breezes, and katabatic winds.

WEBER, ALFRED (1868–1958)

The younger brother of the famed German sociologist Max Weber, Alfred Weber developed an enormously influential model of corporate location based on the minimization of transportation costs that powerfully shaped economic geography, particularly location theory, spatial science, and regional science, for decades to come. Weber's famous model was originally developed for the analysis of manufacturing, although it can be applied to other sectors such as services as well. It was very useful to the exploration of the influence of transportation costs in a rigorous way, and many economic geographers still work in this tradition.

Alfred Weber taught at the University of Heidelberg from 1907 to 1933, when he was dismissed by the Nazis. Although he stayed in the country

during World War II, he played a significant role in the resistance movement of the German intelligentsia. Following the Nazi defeat in 1945, he was reinstated at his old university, where he remained until his death.

Weber's approach emphasizes the role of transportation costs in the location decisions of individual companies. He attempted to determine the patterns that would develop in a world of numerous, competitive, single-plant firms. Weber began by assuming that transportation costs are a linear function of distance, that producers face neither risk nor uncertainty, and that the demand for a product is infinite at a given price—that is, producers could sell as many units as they produced at a fixed price. Firms encountered costs of moving inputs, or backward linkages from suppliers and raw materials, as well as outputs, or forward linkages to clients in the market (Figure 1). The best location for a manufacturing plant is the point at which total transportation costs, that is, costs of transporting inputs plus outputs, are minimized.

The costs of moving supplies and materials vary according to their weight and the degree to which they are used in the production of each good, leading firms to be either resource or market oriented. Thus, firms for which the costs of moving inputs are greatest (weight-losing industries) tend to locate near the site of raw materials, such as mining companies, while those for which the costs of transporting goods to market (weight-gaining industries) are greatest tend to be market oriented, such as bottled-drink manufacturers (Figure 2). Weber modeled this process both mathematically and using physical weights and drew lines of equal

Figure 1 All firms must confront purchases of inputs (backward linkages) and sales of output (forward linkages), which are mediated over space by transport costs.

Source: Author.

Figure 2 Transport cost structure of raw material and market-oriented firms. Firms face the costs of moving raw materials (RM) and final products (FP), which when combined create total transport costs (TTC) that are minimized either at the site of inputs (A) or at the market (B).

Source: Author.

total transport costs called *isodapanes*. The optimal location, he further maintained, would also be influenced by spatial variations in labor costs and by agglomeration economies.

Despite its broad appeal, there are several developments that limit its applicability. First, not all firms need to minimize transport costs; given the rent-transport trade-off that all firms must make, some firms will accept higher transport costs and locate on the urban periphery to minimize rents. Second, the production process is much more complex than it was in the early 20th century, when Weber developed his model. Many plants begin with semifinished items and components rather than with raw materials. Producers' goods seldom lose large amounts of weight; therefore, there is not much tendency toward material orientation. Weber's model has also been criticized for its unrealistic view of transportation costs as a linear function of distance. Because of fixed costs, especially terminal costs, long hauls cost less per unit of weight than short hauls do. Plants tend to locate at material or market points rather than at intermediate points, unless there is an enforced change in the transportation mode, such as at a port. However, with the expansion of the modern trucking

industry and its flexibility in short hauls, the disadvantages of intermediate locations have been reduced.

Finally, other developments have a bearing on how industrial location choices have changed. Transportation costs have been declining in the long run and now constitute a relatively small share of the final costs of most goods. This decline increases the importance of other locational factors, particularly labor costs and productivity. This trend is most obvious in firms producing high-value products. Yet for firms that distribute consumer goods (e.g., soft drinks) to dispersed markets, transportation costs remain a significant factor. Second, natural resources are no longer as important in the growth of economies as they were historically. Instead, there has occurred a widespread trans-materialization of resources as smaller, lighter products are made from resources to which high technology and brainpower have been added. Finally, real-world patterns are evolutionary, not the result of decisions made by optimizers at one moment in time. Most real-world decisions do not result in the best (the most profitable) locations, and locational decisions, once made, often lead to industrial inertia, the tendency to

continue investing in a nonoptimal site even if more optimal locations exist.

WEB GEOPROCESSING WORKFLOWS

The rapid evolution from monolithic desktop geographic information system (GIS) applications with tightly coupled geodata to spatial data infrastructures (SDIs) with independent, interoperable, and distributed Web services has changed the GIS world fundamentally. Nevertheless, the existing SDIs are focused on data retrieval and visualization. To generate information out of data, it becomes necessary to process the data. However, the complexity of spatial data often requires the functionality of several geoprocesses and has led to Web-based geoprocessing workflows. The Web-based geoprocessing workflows can be viewed as a combination of two fundamental concepts: geoprocessing and workflow in a service-oriented and Web-based context.

Geoprocessing

In the absence of a general definition, the term *geoprocessing* can be seen as a specialization of

the term processing in a spatial context. In other words, geoprocessing is the processing of spatially related data. In classical desktop GIS applications such as GRASS or ArcGIS, geoprocessing represents the core GIS analysis functionality and thus is one of the key concepts. In contrast to monolithic desktop GIS, distributed GIS are based on loosely coupled services organized in SDIs. According to the ISO 19119 specification, there are four different types of geoprocessing services:

1. Spatial processing, such as coordinate transformation services, feature manipulation services, or route determination services
2. Thematic processing, such as thematic classification services, geographic information extraction services, or image processing services
3. Temporal processing, such as temporal reference system transformation services, subsetting services, or temporal proximity analysis services
4. Metadata processing, such as statistical calculation services and geographic annotation services

From the work of the Open Geospatial Consortium, the Web Processing Service specification evolved as a standardized but generic service approach to perform geoprocesses in an SDI on distributed data. These processes can be as simple as the sum of two numbers (e.g., population) or as complex as a global climate model. The data required by the service can be delivered across a network or made available on a server. Image data formats or data exchange standards such as geography markup language or KML can be used to encode the data. The Geoprocessing Web Services form the building blocks for Web-based geoprocessing workflows.

Web-Based Workflows

The term *workflow* was defined by ISO 19119 as “the automation of a business process, in whole or part, during which documents, information or tasks are passed from one participant to another for action, according to a set of procedural rules.”

This concept of a workflow has been extensively researched in the information technology (IT) and business fields for several decades. With the advent of the service-oriented architecture paradigm and the increasing data-processing power of network computing, Web-service-based workflows are currently a prominent workflow type. By integrating several Web services from different partners into a single workflow, it becomes possible to form virtual enterprises. These concepts of Web-based workflows rely heavily on service chains to exchange information between workflow participants. There are three different architectural patterns defined for service chains according to ISO 19119:

1. User transparent chaining
2. Translucent chaining
3. Opaque chaining

Especially the opaque chaining pattern is applied by the “mainstream” IT workflow management systems, which mostly use the idea of Web service orchestration (WSO). This concept is defined as a description of how composed Web services interact on the message level. The description includes the business logic and execution order. Based on the predefined message exchange protocol, the interaction is controlled by a central orchestration engine that enables the Web services to be held loosely coupled. This common central orchestration approach is widely supported by several major IT WSO frameworks. The frameworks allow the visual composition of workflows instead of programming and hence enable flexible and rapid workflow modeling and execution. The Business Process Execution Language is mainly used by these frameworks since it is the de facto standard.

Web-Based Geoprocessing Workflows

Web-based geoprocessing workflow brings both terms together. It can be seen as an automation of a spatial process/model, in whole or in part, during which geoinformation is passed from one distributed geoprocessing Web service

to another according to a set of procedural rules and standardized interfaces. In other words, Web-based geoprocessing workflows integrate loosely coupled spatial data and services in an interoperable way, where each part of the workflow is responsible for only a specific task, without being aware of the broader purpose of the workflow. Especially in highly specialized environments such as the GI domain, not every processing step can be potentially handled by a single entity, and therefore, geoprocessing workflows have to be formed. Therefore, outsourcing specialized tasks to highly specialized Web services becomes necessary. As a result, workflows become flexible and are able to quickly adapt to changing market conditions thus leading to higher flexibility and scalability of geoprocesses.

The idea that geoprocessing workflows should be flexible and scalable reflects the general transition from a supply-driven economy to an on-demand economy in the geodomain. Therefore, Web-based cross-enterprise geoprocessing workflows as virtual business processes can be formed by integrating several processes from different partners while still being regarded as a single process from an external point of view.

Due to the distributed nature of geographic data, geoprocessing workflows provide a flexible means for the processing of highly distributed and complex data for a wide variety of applications. The aggregation of existing geoprocessing workflows, exposed as Web services or wrapped by Web services, into a single workflow uses the powerful and flexible capabilities of Web-based geoprocessing workflows.

The full potential of Web-based geoprocessing workflows as an integration platform has already been demonstrated by several research communities. However, further progress of this technology and its broader adoption require that advances be made in the areas of semantic geodata interoperability and in the legal aspects of geospatial information.

WEB SERVICE ARCHITECTURES FOR GIS

There have been many successful developments of geographic information systems (GIS) serving different purposes and different organizations and using different GIS software packages. However, geospatial information sharing and acquisition remains a challenge due to the heterogeneity of existing systems in terms of proprietary system designs, data models, and database storage structures. The emergence and use of Web services and Web-service-oriented architecture (SOA) technologies offer the potential to overcome barriers to interoperability among heterogeneous GIS.

Service-Oriented Architecture

The SOA was developed by IBM, Microsoft, and other leading IT industry organizations to support the development of applications that integrate existing computing technologies into

solution-based systems. A pure architectural definition of SOA presents it as a design within which all functions are defined as independent services with well-defined and invokable interfaces. An SOA is essentially a collection of Web services that communicate with each other by passing simple data or coordinating some activities. IBM has created a model for an SOA that describes three roles—(1) service provider, (2) service requester, and (3) service broker—and three basic operations—(1) publish, (2) find, and (3) bind. Service providers publish services to a service broker. Service requesters find required services using a service broker and bind to them. The binding from the service requester to the service provider should loosely couple the service. This means that the service requester has no knowledge of the technical details of the provider's implementation, such as the programming language, deployment platform, and so forth. Because Web services in SOA are based on open standards, they are able to work together and understand each other even though they don't use the same language or share the same application platform. For example, the data service "Wisconsin land use map"—residing on a Microsoft Windows server in Wisconsin—can be invoked by the service "display Wisconsin land use map" written in Java code and residing on a Linux server in Los Angeles.

To implement an SOA, the open-standard specifications—WSDL (Web Service Description Language), SOAP (Simple Object Access Protocol), and UDDI (Universal Description, Discovery and Integration Service)—are developed to support the interaction of Web services. The WSDL is an Extensible Markup Language (XML)-based language used to describe the services that a business offers and to provide a way for individuals and other businesses to access those services electronically. A complete WSDL definition contains all the information necessary to invoke a Web service, such as what a Web service can do, where it resides, and how to invoke it. It provides a way for service providers to describe the basic format of Web service requests over different protocols or encodings and thus helps improve interoperability between applications. The SOAP is a

communication protocol for communication between applications running on different operating systems with different technologies and programming languages. It defines a format for sending messages between communicating applications via the Internet and specifically using Hypertext Transfer Protocol (HTTP). SOAP consists of three parts: (1) an envelope that defines a framework for describing what is in a message and how to process it, (2) a set of encoding rules for expressing instances of application-defined data types, and (3) a convention for representing remote procedure calls and responses. UDDI provides a mechanism for clients to dynamically find other Web services. Using a UDDI interface, users can dynamically connect to services provided by external providers. The provider typically publishes a WSDL description of its Web service, and the requester accesses the description using a UDDI or other type of registry and requests the execution of the provider's service by sending a SOAP message to it. Since all data in SOA are tagged in XML, communication between applications doesn't depend on any particular operating system or programming language.

Web Service Architectures for GIS

A Web service architecture for sharing geospatial data and geoprocessing models over the Web is illustrated in Figure 1. The main objectives of the Web service architecture for GIS are to (a) maximize productivity and efficiency with geospatial data and online geoprocessing sharing, (b) overcome spatial data and GIS model duplication and maintenance problems, and (c) make it easy to integrate different GIS applications.

The Web service architecture for GIS is based on independent OGC Web services. It is composed of three elements: (1) service provider, (2) service broker, and (3) service client. The service provider supplies geospatial data and geoprocessing models, the service client allows users to search and integrate geospatial data and geoprocessing models from providers, and the service broker provides a registry for available services. The service provider uses OGC data services such as WFS (Web Feature Services), WMS (Web Map Services), and

WCS (Web Coverage Services) to publish geospatial data and WPS (Web Processing Services) to publish geoprocessing models connected to existing heterogeneous GIS such as GIS1 and GIS2 (Figure 1). The service broker uses OGC WRS/CS (Web Registry Services/Catalog Services) instead of using a UDDI to register and manage the OGC data and processing services and allow users to search for these Web services over the Web. Service clients search the contents of catalog services to find the data sets and services of interest, and they also can combine the OGC Web services found through catalog Web services.

A catalog service can publish and search for collections of the resource-based metadata information, and it has two main functions—discovery and publication. Discovery means that the service requester seeks to find resources of interest through simple browsing or by sophisticated query-driven discovery that specifies simple or advanced search criteria. The catalog performs the search and returns a result set that contains all registry objects that satisfy the search criteria. The requester may then choose to retrieve representations of result set items according to some specified schema and element set. The OGC catalog service supports distributed search. That means that a catalog service can interwork with other affiliated catalogs to enlarge the total search space. When a catalog is linked to a peer catalog, it makes the resource descriptions managed by the peer implicitly available to its own clients. The propagation of request messages to the affiliated catalog is invisible to the client—it is not necessary to know where the metadata repositories are located or how they are accessed. A catalog service allows Web services to publish resources in two ways: (1) harvest operation and (2) transaction operation. Harvest operation is the basic publication, and in this operation the catalog itself attempts to harvest a resource from a specified network location, thereby realizing a “pull” model for publishing registry objects. If the catalog successfully retrieves the resource and can handle it, then one or more corresponding registry objects are created or updated. The second way of publication is transaction operation, which is enhanced publication. Transaction operation supports modifying catalog content through a public interface that allows a

Figure 1 Web service architecture for GIS

Source: Author.

“push” style of publication. A user may insert, update, or delete catalog entries according to criteria specified in the request message. Typically, this operation is subject to some kind of access control such that only authorized users may perform such actions.

As illustrated in Figure 1, the Web services in the SOA for GIS are achieved via WSDL by connecting service providers, service brokers, and service clients. The SOAP binding over HTTP is employed for communication between Web services via the Internet. The SOA ensures data interoperability through the standard exchange

mechanism between diverse GIS sources connected over the Web.

The main benefit of the SOA is that it allows the sharing and integration of spatial data and geoprocessing models from diverse sources transparently across the Web. That is, the SOA allows geospatial data and GIS models to be shared and reused across applications, enterprises, and community boundaries. Thus, many existing proprietary GIS legacy databases and models may be reused and shared. With a ubiquitous set of standards in the SOA, users are capable of creating applications that can be built on top of existing

applications. In addition, the SOA allows geoprocessing to be carried out by chaining (linking) several services representing relatively independent, distributed applications. With its loosely coupled structure, the SOA permits smart and fast updating of the system's obsolete data and models and quick integration of new data and models into the application system, thus enhancing the flexibility and reuse of spatial data and GIS models. Therefore, it may reduce the cost of developing new application programs and leverage an organization's existing investment in data and applications.

Although the Web SOA offers the aforementioned advantages, it presently only resolves technical interoperability through Web services and standard interfaces, and it stops short of resolving the semantic heterogeneity problem in existing GIS. One possible approach to overcoming the problem of semantic heterogeneity is developing domain-specific ontologies and semantic interoperability systems. The concept of Geospatial Semantic Web has been suggested recently to address the vexing challenges of semantic interoperability.

WETLANDS

Wetlands are lands that are significantly influenced by the presence of water. Although relatively rare, these fragile ecosystems, which occupy approximately 6% of Earth's surface, are found on every continent except Antarctica. Wetlands are found in most of the world's climatic zones, ranging from warm tropical climates to frigid arctic climates. They are present across a wide range of elevations around the world, from below sea level to mountaintops.

Wetlands are broadly classified according to topography and water salinity. Topographically, they may be present in either coastal areas or inland. When subdivided according to water salinity, they may range from saline (salinity ≥ 30.0 parts per 1,000) to brackish (salinity 29–0.6 part per 1,000) to fresh (salinity ≤ 0.5 part per 1,000). The salinity of coastal wetlands is influenced by distance from the ocean, tides, topography, and the presence and discharge of various sources of freshwater, such as rivers and groundwater. Examples of coastal wetlands include cord grass (*Spartina* sp.)–dominated tidal marshes and mangrove (*Rhizophora mangle*, *Avicennia* sp., *Laguncularia racemosa*, *Sonneratia* sp.) swamps.

The vast majority of interior wetlands are freshwater; however, saltwater interior wetlands may occur in arid regions. Interior wetlands are subdivided according to the environment in which they occur. Major classes of interior wetlands include riverine (river environment), palustrine (pond, pothole environment), and lacustrine (lake environment). Cattails (*Typha* sp.) and rushes (*Juncus* sp.) are plants commonly found in interior wetlands.

Regardless of the environment where a wetland is located, all wetlands share three characteristics: (1) wetland hydrology, (2) hydric (i.e., wetland soil), and (3) hydrophytic vegetation. Water within a wetland may be permanent, inundating the area year-round, or it may be seasonal or ephemeral, flooding an area only a few weeks or months of the year. Prolonged flooding, particularly during the growing period, significantly affects the soil and the vegetation of wetlands.

Given time, continued soil saturation dramatically influences the chemical and physical

Canada geese, common egret, and shore birds in a pothole wetland in South Dakota. Wetlands provide a haven for migrating ducks, geese, and other waterfowl.

Source: Dennis Larson, USDA Natural Resources Conservation Service.

composition of the soil. The upper portions of soil become anaerobic (i.e., without oxygen). Hydric soils have either an organic or a mineral texture. Organic hydric soils are composed mainly of vegetation with varying degrees of decomposition. Muck and peat are common examples of an organic wetland soil. Mineral hydric soil contains little organic matter. This type of soil develops readily identifiable characteristics, such as gleying and mottling. Gleying is a process that occurs in anaerobic, waterlogged soils where iron present in the soil is chemically reduced to iron oxide because of the lack of oxygen. This results in a soil that has a distinctive blue-gray or greenish color. Mottles may also develop from the reduction of iron. Mottles are small, generally

pea-sized or less, reddish-brown or yellowish specks/spots found in dark wetland soil.

Saturated anaerobic conditions influence the type of vegetation that occurs within wetlands. Wetlands vegetation may develop morphological adaptations, which allow the vegetation to thrive in saturated conditions. Common adaptations include shallow root systems, adventitious roots, pneumatophores, multiple trunks, and buttress trunks. Adventitious roots and pneumatophores are some of the more interesting adaptations. Adventitious roots are roots that may develop from the stem or branches of a plant at points above the soil. Pneumatophores are roots that protrude through soil and surface water, thus allowing plants to obtain oxygen in an otherwise

anaerobic environment. Both mangroves and bald cypress (*Taxodium distichum*) develop extensive networks of pneumatophores.

Wetlands are extremely important habitats for humans and wildlife. Coastal wetlands are some of the most productive ecosystems in the world, serving as nursery grounds for much of the world's commercial fisheries. Coastal wetlands also serve as storm buffers, absorbing storm surges and waves associated with tropical and extratropical weather systems. Both coastal and inland wetlands store excess rainfall and floodwater and act as sinks and filters for waterborne contaminants such as heavy metals, and pathogens such as *Escherichia coli*. Many interior wetlands serve as recharge zones for groundwater aquifers. Wetlands are also critical habitats for myriad wildlife, especially waterfowl (see photo).

Even though wetlands are critical to the survival of many species of plants and animals, they are being destroyed at a very rapid rate. Globally, approximately half of all wetlands have been destroyed since 1900. Wetlands are under intense pressure from humans, who drain them for urban, industrial, and agricultural purposes. Coastal zones are under constant threat from global warming and associated sea level rise. Rising seas are inundating and destroying coastal wetlands.

Several international organizations promote wetland research, conservation, and restoration. Two of the most notable organizations are the Society of Wetland Scientists, which supports scientific wetland research, and Wetlands International, which advocates conservation and restoration. In 1971, an international convention on wetlands was held in Ramsar, Iran. The convention, known as the Ramsar Convention (Ramsar), developed an international treaty, titled the Convention on Wetlands of International Importance Especially as Waterfowl Habitat, to conserve wetlands worldwide. To date, 158 countries have signed this treaty. Ramsar also created and maintains a list of threatened wetlands. The list, called "Wetlands of International Importance," includes more than 1,800 wetlands located throughout the world that are considered critical to wildlife. New wetlands are added to the list annually.

Wetlands are important ecosystems that protect humans from storm surges, filter contaminants

from water, and provide habitat for economically viable wildlife. These fragile environments are under increasing pressure from humans, who drain and destroy wetlands, and from changing climates. More research, conservation, and restoration are needed to protect this valuable resource for future generations.

WHITE, GILBERT (1911–2006)

Gilbert Fowler White was a prominent and influential American geographer, known as the father of floodplain management in the United States, although his environmental research and policy influences extended to water resources and global environmental issues. He was an advocate of practical applied research to improve the human condition. White was born in Chicago, grew up near the University of Chicago campus, and spent summers working on a ranch in Wyoming. He credited both environments with helping shape his research interests and perspectives.

Having satisfied all the requirements for a doctorate except the dissertation at Chicago, White accompanied his PhD advisor, Harlan Barrows, to Washington, D.C., in 1934 to work for the Mississippi Valley Committee of the Public Works Administration. The tenure in Washington was

anticipated to last 6 months, but 8 years later, White was still there. He worked as a staff member for a number of committees and commissions related to natural resources and flood control. The government service helped provide White with a research agenda and skills to implement the policy implications of research.

His Quaker convictions precluded his working for the federal government during World War II, so he left to complete his doctoral dissertation prior to performing relief work in France and then being interned in Germany. His dissertation, *Human Adjustment to Floods*, is seen by many as the seminal work leading to the widespread adoption of nonstructural alternatives to dams and levees to cope with flood hazards in the United States. White himself characterized his dissertation as a call to consider a broad range of possible adjustments to floods and to fully evaluate all the consequences of each adjustment. *Human Adjustment to Floods* led to the field of floodplain management.

After World War II, White became president of Haverford College, before returning to the University of Chicago in 1955 as a professor of geography. At Chicago, he initiated a program of research on natural hazards, much of which evolved from ideas put forth in his dissertation. He mentored numerous students who made their own contributions to natural hazards research, education, and policy, effectively establishing the foundations of the hazards research paradigm still practiced in geography. In 1970, White moved to the University of Colorado, where he continued his hazards research activities, became director of the Institute of Behavioral Science, and eventually founded the interdisciplinary Natural Hazards Research and Applications Information Center. The center continues to serve as a clearinghouse for hazards research and policy, helping provide a bridge between hazards researchers and practitioners.

Although best known in the United States for his contribution to natural hazards research, White was active in many other environmental spheres. His research conducted with the epidemiologist David Bradley and White's wife, Anne U. White on domestic water use in East Africa served as a model for other researchers in other locations. White felt that international cooperation

on river basin development could facilitate other forms of peaceful relations among nations and chaired an advisory group to the United Nations on the Lower Mekong River. White published prolifically throughout his career, until a few years before his death. He served on many national and international committees, commissions, and advisory groups dealing with a wide range of environmental issues, including climate change, water supply, human-made lakes, pollution, the environmental effects of nuclear war, nuclear waste storage, and hazards other than floods.

He served as president of the Association of American Geographers (1961–1962), was elected to the National Academy of Sciences (1973), and received the National Medal of Science (2000) from the U.S. president. Although White was modest about his influence on public policy, others felt that his impacts were significant, often through the actions of his students and followers or because of the way of thinking he brought to many environmental issues. White passed away in Boulder, Colorado.

WHITENESS

Associated with archaic terms such as *Aryan*, *Teutonic*, *Anglo-Saxon*, and *Caucasian* and often assumed to be an inherited biological reality, whiteness is in fact a socially, historically, and geographically constructed understanding of racial identity. Usually constructed against a perceived nonwhite other, there are multiple lived experiences of whiteness, varying across time and space and differing by scale. Understandings of whiteness shape both sparsely populated rural areas and multiracial urban locations, albeit in different ways, and there is no singular, essential white identity.

Whiteness is most commonly associated with pale, pinkish-colored skin and people of Northern European descent. European colonial and U.S. expansionist practices were central to the construction of modern racial whiteness. In the 19th century, U.S. national identities such as Irish and Italian were often envisaged by the elites of Northern European descent as a stepping stone between the inferior African black race and the superior white Anglo-Saxon. Strategies such as employers hiring European immigrants rather than African Americans, and the subsequent benefits of unionization, saw associations develop between whiteness and working-class identities in the United States. As a result, people of these formerly disparaged European nationalities achieved whiteness, so to speak, and gained the benefits of a white racial identity in a racially segregated society. In the 20th century, throughout the United States, associations between whiteness, wealth, and power were strengthened by the construction and maintenance of racialized landscapes such as sundown towns and whites-only suburbs.

In industrialized Western societies, a myth of color blindness developed in the late 20th and early 21st centuries, rendering whiteness largely unexamined. Consequently, discussing whiteness is, to some extent, a taboo subject, except among explicit racists whose appeals to white identities are often linked with hate groups such as neo-Nazis or the Ku Klux Klan. Recognizing the negative associations of overt appeals to whiteness, many white people avoid using the term *white*, instead articulating whiteness through discourses of normality, nature, nationality, culture, and

landscape. For example, some espouse the need to preserve the “European” heritage or to protect specific cultures. In this manner, demands that whiteness be politically recognized are made using the language of multiculturalism and cultural pluralism and through rhetorical appeals to heritage, tradition, ethnicity, and genealogy.

An associated concept is that of white privilege. This refers to the everyday unearned structural advantages that accrue to people whom others identify as white. Often unconscious and unrecognized by the beneficiaries, arguably because of the taboo surrounding articulations of whiteness, white privilege structures Western societies in a manner that positions the values and beliefs of the white (and usually middle class) population as the norm against which the behaviors and practices of others are contrasted. Commonly associated with the practices of institutionalized racism, white privilege reconfigures understandings of racism to explain the advantages gained from whiteness. These advantages, however, vary with the shifting boundaries of whiteness and are reconfigured by class, gender, sexuality, age, and other demographic characteristics.

WHITTLESEY, DERWENT (1890–1956)

One of the more important figures of cultural geography in the early to mid 20th century, Derwent Stainthorpe Whittlesey is best known for advocating the notion of sequent occupance. He served as president of the Association of American Geographers (AAG) in 1944 and was editor of the *Annals of the Association of American Geographers* for 12 years.

Born in the farming community of Pecatonica, Illinois, Whittlesey studied at the University of Chicago, where he completed a degree in history in 1915; he then attended the School of Geography, where he studied under Ellen Churchill Semple and Harlan Barrows. After graduation, he taught at Chicago from 1920 to 1928, when he moved to Harvard to become its first human geographer; for the remainder of his career, he was professor of cultural and political geography at Harvard. He served as a consultant for the U.S. state, war, and navy departments during World War II. His interest in political affairs led him to publish *The Earth and the State* in 1939 and, with two coauthors, *German Strategy for World Conquest* in 1942. Whittlesey delved into several other topics, including agricultural development and the nature of regions and regionalism. He also studied Africa for 35 years, particularly Rhodesia (now Zimbabwe). His work historicized cultural and political issues in an era when much of geography viewed the world in static, ahistorical terms.

In 1929, Whittlesey introduced the term for which he is best known, *sequent occupance*—a technique for analyzing landscapes as the product

of successive groups over time, each of which uses it in its own way and leaves a lasting imprint. Landscapes are thus created by the number of groups that occupied an area at different moments, and comprise a palimpsest. To understand the landscape was to understand the history and practices of its various groups of inhabitants, each of which created a spatiality that both reflected that of its predecessor and subsequently influenced that of its successor. Each group, he argued, carried the seeds of its own transformation; culture was thus never a frozen set of ideas or objects but was continually in motion. In framing this issue, Whittlesey drew selectively from human ecology, but he forcefully offered a social dynamic at odds with the deterministic erosional cycle of William Morris Davis, which was then the dominant means of interpreting landscapes. In this respect, Whittlesey shared much in common with Carl Sauer, that is, a view of cultural landscapes as ever changing and historically generated, as produced rather than given; both played a vital role in combating environmental determinism. Sequent occupance would later find its way into the resurrection of localities research in the late 20th century.

As president of the AAG in 1944–1945, Whittlesey published his presidential address when the annual conference was canceled to curtail wartime travel. His essay “The Horizon of Geography,” published in 1945, deftly summarized the changing scale of spatial consciousness that accompanied humanity’s ascent from hunting and gathering to the modern age: “By scrutinizing successive space-horizons from the most primitive known down to the present, it should be possible to determine the character and limits of geographic space in the present world of revolutionary technology and social adaptation” (p. 3).

One of the most famous events concerning Whittlesey was the closure of the Harvard geography department in 1948, of which he was the chair. In a period in which the discipline, dominated by empiricist chorology, was not known for intellectual vitality, the closure marked the first of a long series. The department fell under sustained attack from geologists and from Harvard’s president, who felt that geography did not qualify as a university discipline. Isaiah Bowman, the then president of Johns Hopkins University,

could have helped in this situation but chose not to do so, in part because he felt that the Harvard department overemphasized human geography and in part due to his homophobic feelings about Whittlesey, who was widely presumed to be gay. Whittlesey, however, continued to teach at Harvard until his death.

in the North American context. As its definitions have changed, wilderness areas have become contested sites.

During the settlement era, Euro-Americans often feared the wilderness, as it was home to dangerous creatures and seemingly dangerous “others,” the indigenous peoples of the continent. In the 19th century, several influences reworked the meaning of wilderness. The aesthetic and spiritual ideas of Romanticism and Transcendentalism for some transformed the wilderness from a devilish place to a location where one might more easily commune with God. The perceived loss of the frontier, growth of cities, and polluting impacts of industrialization made others look to wilderness as symbolic of a rugged, independent American character that was threatened by urbanization. Wilderness became a therapeutic space.

As these definitions of wilderness took hold, arguments over the purpose of wilderness entered public discourse. In the 20th century, the preservationists, who sought to protect the ecological and aesthetic integrity of the wilderness by leaving areas untouched by development, fought against the conservationists, who strove to extract valuable natural resources using methods that would ensure their continued supply into the future. Around the world, international organizations; federal, state, and provincial governments; and nongovernmental organizations have officially protected lands as wilderness areas. In many instances, the act of drawing boundaries around wilderness areas and, furthermore, defining who and what belongs within such spaces has raised considerable controversy.

In recent years, human geographers have argued that the evolving definition of wilderness is evidence that it is a social construct. This does not mean that wild places do not exist or that their ecological, aesthetic, and spiritual qualities are insignificant but, instead, that notions of wilderness are products of human cultures. Some scholars assert that few designated wilderness areas extant today were ever uninhabited; in many cases, indigenous peoples were removed from their lands to create a wilderness that fits a narrow definition. Others point out that wilderness has class, gendered, and racial dimensions. These ideas are vigorously contested, especially by those who are concerned that resource extraction, pollution,

WILDERNESS

Wilderness is understood as a region that exists in its original, natural state with few or no human inhabitants. It may contain distinctive geographic features, rare ecosystems, or plant and animal species that require vast expanses of land for habitat. Since the 1970s, geographers and environmental historians have closely examined the definition of wilderness. They found that its meaning has changed significantly over time, especially

The Arctic National Wildlife Refuge, pictured here, is home to some of the most diverse and spectacular wildlife in the Arctic. The refuge's rich pageant of wildlife includes 36 fish species, 36 land mammals, 9 marine mammals, and more than 160 migratory and resident bird species.

Source: U.S. Fish & Wildlife Service.

and land development are threatening to permanently damage or even end fragile, irreplaceable, and ecologically important natural areas. For these advocates, the scientific community cannot afford scholarly debates over definitions that might further a political agenda to tamper with wilderness.

WILDFIRES: RISK AND HAZARD

Analysis of the threat, hazard, and risk relative to wildfire is a spatial problem: Where does a wildfire occur relative to resources valued by humans? In the natural or built environment? Wildfires burn uncultivated vegetation in natural environments, whether mountainous forests, rural woodlands, brush lands, or prairie grasslands. In common usage, the terms *threat*, *hazard*, and *risk* are often interchanged and confound understanding of the important distinctions between them.

Any wildfire may be considered to pose a *threat*, to present the potential to do harm. *Threat* refers to the source that could cause damage. A wildfire threat exists where heat from burning vegetation could ignite other combustible material regardless of whether burning that material would constitute a loss. Whether a wildfire poses *hazard* or *risk* depends on whether any valued resources, natural or human-made, that could be damaged by fire are potentially in a path of fire spread. Unless some resource determined to be of value is in harm's way, no hazard or risk is associated with a wildfire.

The term *hazard* may be most effectively used when planning to mitigate potential losses in some future, nonspecified time. Efforts to thin forest fuels around homes well in advance of the wildfire season constitute hazard reduction. This action is taken in the absence of an immediate threat. Fuel reduction usually occurs where it is recognized that the potential for loss would be high if a wildfire were to occur some time in the coming years.

Analysis of risk explicitly requires assessment of the probability that a loss will occur as a result of wildfire. What is the chance or likelihood that a fire will reach and damage or destroy a valued resource? The probability statement may be qualitative, based on some form of actuarial analysis, or derived from quantitative techniques such as numerical fire spread modeling. Strictly applied, *risk analysis* is the calculation of expected loss, the value of the threatened resource multiplied by the expected value change to that resource.

For example, if a fire is ignited on a heavily forested mountain, the mere presence of an active flame is commonly considered to present a threat. If a communications tower is downwind or otherwise in the vicinity of the flames, the fire presents a hazardous condition relative to the tower. This statement of hazard does not assume one way or the other that the fire will actually reach and damage the tower. If the tower is valued at \$250,000 and there is a 50% chance that the fire will reach and destroy the tower, the tower is *at risk*. The expected loss is calculated at \$125,000. This calculation could be extended to loss of services if a value for the loss could be clearly defined.

Analysis of hazard and risk posed by wildfire is fundamentally a two-part spatial problem. It

starts with threat analysis: Where is the fire currently located, and where is it headed? The second part analyzes hazard and risk. Hazard assessment identifies the valued resources that wildfire may intersect as it spreads. Risk assessment considers the probability that valued resources will be damaged or destroyed so that the value will be changed. This spatial intersection of the potential area of wildfire spread with valued resources may be implied by observation and judgment or explicitly determined through rigorous geospatial analysis commonly conducted within geographic information systems.

Fire behavior models predict fire spread, and fundamental spatial analysis evaluates geospatial databases of values potentially at risk (Figure 1). Spatially explicit numerical models calculate the direction and rate of spread of wildfire based on the characteristics of weather, topography, and vegetation. These factors influencing and controlling fire behavior have been determined through observation and experiment. Weather characteristics include the direction and speed of prevailing winds and the influence of temperature, precipitation, and relative humidity on fuel moistures. Topographic or terrain factors include elevation, hillslope gradient or steepness, and aspect, the direction a hillslope is facing. The vegetation or the fuels that may feed a wildfire are defined by surface fuels, the distance between the ground surface and the lowest limbs, the spacing of the crowns of overstory trees, the vegetation bulk density, and the height of the dominant forest or shrub canopy. The current fire location and where the fire will probably spread are mapped with geospatial data of values potentially at risk. Many data sets are available that represent critical infrastructure such as electric power lines, oil and gas pipelines, and locations of public buildings and recreational facilities on public lands. These data sets are improving and expanding, driven by commercial and national security needs.

Assigning a value to the resources at risk may be very simple or complicated. Clear dollar values may be assigned to objects in the built environment. Dollar amounts typically represent the cost of repairing or replacing any items damaged or destroyed by a wildfire. Often, no clear market value exists for the valued natural resources. For example, what is the value of an isolated

Figure 1 Risk assessment map for the Whiskeytown Fire near Redding, California, 2008. The rainbow array represents the area of probable fire spread predicted by the Fire Spread Probability (FSPRO) model of the USDA Forest Service. Fire spread is mapped relative to threat.

Source: Author.

population of an endangered plant or the value of clean water? Two problems commonly arise while assessing the hazard or risk to such resources. The first problem is what economists refer to as the valuation of nonmarket resources—a highly controversial area of economic theory. One nonmonetary, indirect solution to this is to simply summarize the amount of nonmarket resources by area, linear distance, or item count within the area into which a fire may spread. Another difficulty comes where the wildfire might ultimately benefit ecosystem health. Wildfire is a natural process within forests, grasslands, and shrub ecosystems, a process to which many species are adapted and without which they fail to thrive. Wildfire may be necessary to maintain or restore ecosystem health and functionality. This problem is compounded by the source of ignition: Is the fire caused by a “natural” lightning strike or by humans? When a fire is caused by humans, it may be considered unnatural even if the possible outcome could be beneficial to the ecosystem.

Given the conflict between the potential benefit of wildfire and the potential for loss of valued resources, the analysis of trade-off is inherent in the assessment of hazard and risk presented by wildfire. In the short-term, a wildfire may destroy a lookout tower atop a mountain. However, the same fire could lead to the regeneration of fire-dependent tree species and improve ecosystem health through trophic cascading benefits. For example, a wildfire could ultimately spur regeneration of whitebark pine, which produces seeds that provide highly enriched hibernation food for the endangered grizzly bear.

WILSON, JOHN (1955–)

John Wilson is one of geography's leading practitioners of geographical information systems (GIS), particularly in the context of environmental concerns. He is a professor of geography at the University of Southern California, where he chairs the department of geography, directs the geographic information science and technology graduate programs as well as the GIS research laboratory, and also holds adjunct appointments as professor in the departments of computer science and civil and environmental engineering. He received his PhD in geography from the University of Toronto, Canada, in 1986. He also holds an LLB honors law degree from the University of Canterbury, New Zealand.

From 1992 to 1997, he was a professor of geography in the department of Earth sciences, an adjunct professor of soil science in the department of plant and soil science, and the director of the Geographic Information and Analysis Center at Montana State University. His early career included positions as assistant professor (1984–1990) and associate professor (1990–1994) of geography, with corresponding adjunct appointments in soil science at Montana State University. He founded the Geographic Information and Analysis Center at Montana State University in 1989 and the GIS Research Laboratory at the University of Southern California in 1997. He has held several visiting appointments in environmental

studies, geography, and planning at the Australian National University, the University of Utrecht in the Netherlands, and the University of Waikato in New Zealand.

Wilson's research builds on physical, human, and quantitative emphases in geography. His master's research investigated internal migration in the Gilbert and Ellice Islands Colony using the 1973 census data, and his doctoral dissertation analyzed environmental change in the Lake Simcoe Basin. Nevertheless, his research culminates in GIS tool development, spatial analysis, and environmental modeling. He has published numerous books and articles on these topics, including two edited volumes, *Terrain Analysis: Principles and Applications* in 2000 and the *Handbook of Geographic Information Science* in 2007. He is one of the leading geographers actively involved in collaborative, multidisciplinary research with the goal of improving knowledge and understanding of the human impact on both the natural and the built environment. Many of his research projects (see www.uscgislab.net) not only contribute to geography but also broaden geographic perspectives to a wide range of academic communities. He has received numerous honors for his research and teaching, the most recent being a Mellon Award for Excellence in Mentoring from the Center for Excellence in Teaching in 2005 and an Albert S. Raubenheimer Outstanding Faculty Award for his research, teaching, and service contributions in 2004, both at the University of Southern California. He has received accolades outside academia with the Special Achievement in GIS Award for Leadership With Geospatial Technology from the Environmental Systems and Research Institute in 2006 and 2008.

Wilson has also led national and international efforts to strengthen academic communities in GIS. He founded the journal *Transactions in GIS* in 1996 and has served as its editor-in-chief since its inception. He has served on the editorial boards of *Applied Geography* and *Annals of the Association of American Geographers*. He chaired the Applied Geography Specialty Group of the Association of American Geographers (1989–1991) and the Research Committee of the University Consortium for Geographic Information Science (2002–2005). He served as president of the University Consortium of Geographic Information

Science in 2006–2007 and is an active participant in the UNIGIS International Network—a worldwide consortium of more than 20 institutions that collaborate on the development and delivery of online geographic information science academic programs.

WIND

Wind is a fluid motion in an atmosphere. All wind is caused by pressure differences. Wind is ubiquitous but varies considerably in its spatial and temporal scales and has a significant impact on the human and physical components of Earth.

Humans have long been fascinated by the wind. For example, several references to wind are found in the Bible. In Greek mythology, Aeolus was the custodian of the four winds. Evangelista Torricelli, who invented the barometer, provided the first scientific description of wind formation in the mid 17th century. We now have the capability of measuring wind from space and have garnered enough information about wind patterns to

predict weather and generate power from wind, for example. This discussion of wind is organized around four themes: formation, types, measurement, and importance.

Formation

Horizontal differences in pressure can cause air movement, or wind. Atmospheric pressure, air density, and air temperature are interrelated. Warm air temperatures increase the air's molecular velocity, decrease air density, and cause air pressure aloft to rise. Cold temperatures increase air density and cause air to sink, thus lowering the air pressure. Generally, airflow is from high to low pressure, compared across uniform height above the surface, with wind velocity increasing with increasing pressure differences. The difference in pressure between two places divided by the horizontal distance between two places is called the pressure gradient. Tightly spaced isobars (lines indicating equal pressure) on a weather map indicate increased pressure gradients. Larger pressure gradients are associated with larger pressure gradient forces. Newton's second law of motion predicates that the relationship between pressure gradient force and wind speed is positively linear.

In addition to pressure gradient force, several other forces influence wind speed and direction. Coriolis force (after Gaspard Coriolis), or effect, is an apparent force resultant from Earth's rotation. Coriolis force opposes pressure gradient force, causes wind deflection, and does not affect wind speed. Deflection is toward the right and left in the Northern and Southern hemispheres, respectively. Deflection magnitude depends on wind velocity and latitude. Increasing latitude corresponds with increasing deflection, with no deflection at the equator. Centripetal acceleration affects airflow around circulation centers and influences wind direction but not speed. Centripetal acceleration steers winds at right angles to the rotational center of the low pressure. The fourth force is friction, which opposes the dominant wind direction and causes a deceleration. Frictional effects are only found close (less than 1 kilometer) to Earth's surface.

Global and upper-level wind circulation can be conceptualized using Hadley's (after George

Hadley) three-cell model in which the Hadley (0° – 30°), Ferrel (30° – 60°), and Polar (60° – 90°) cells are found in both the hemispheres (Figure 1). The Hadley cell is a convection loop; warm equatorial air rises and moves aloft, laterally to the poles, cooling as it approaches the middle latitudes (30°). The rising equatorial air produces the equatorial trough, and surface air converges. The region of convergence is the intertropical convergence zone (ITCZ), its exact location fluctuating throughout the year between approximately 25° N and 20° S. ITCZ controls monsoons, a phenomenon primarily influencing the northeast Indian Ocean region. The region between 0° and 30° is the doldrums, and warm air and weak horizontal pressure gradients dominate. The poleward extreme of the Hadley cell at 30° N/S is dominated by convergent air aloft descending to the surface, thus increasing surface air pressure (the subtropical highs). The resultant generalized weather around 30° is warm surface temperatures and relatively cloudfree skies. Earth's major deserts (e.g., Sahara) are found here. The horse latitudes are an informal name for 30° N/S. Ships traveling to the New World were greatly slowed from the weak pressure gradients and winds. Legend indicates that as travel time increased, food decreased and horses were eaten or evacuated overboard. Winds divert poleward and toward the equator from the subtropical high-pressure systems. The equatorward winds are the northeast (Northern Hemisphere) and southeast (Southern Hemisphere) trades; these relatively steady winds were named so because they provided sailing ships with routes during merchant trading.

The pressure and wind patterns of the Ferrel cell (after William Ferrel) are more complex than those of the Hadley cell. The poleward winds originating around the subtropical highs at 30° are the westerlies; wind deflects to the east in both hemispheres. The westerlies converge with the polar easterlies around 60° . The converging air at 60° does not readily mix, mainly because of contrasting temperatures. The boundary between the two air masses is the polar front, a low-pressure zone. The weak polar cell circulates poleward aloft, descends at the poles, and moves horizontally toward 60° on the surface (westerlies) where air rises. The latitudinal extents described in the Hadley three-cell model are

Figure 1 Idealized global circulation according to Hadley's three-cell model, disregarding the effect of landmasses

idealized. Actual locations are influenced strongly by seasons and the different heating and cooling characteristics of land and water.

Types

Jet streams are fast-flowing air currents that are thousands of kilometers long, a couple of hundred kilometers wide, and a few kilometers thick; they are found between 10 and 15 km above the surface. There are two jet streams: (1) subtropical,

fluctuating about 30°, and (2) polar, fluctuating about 60° and influenced by the Rossby waves.

Surface winds range in scale from meters to thousands of kilometers, and their air temperature differences have different causes. Land-sea breezes typically direct wind from the land to the water in the evenings, when lower temperatures and higher pressure are observed on the land, compared with higher temperatures and lower pressure observed over the water. These winds are strongly influenced by the high thermal holding

capacity of water. Various regional names (e.g., *mistral* in Southern France and *taku* in Alaska) are used to describe katabatic drainage-type winds; cold dense air accumulates in high valleys or plateaus and descends (in altitude) due to gravity. “Snow-eating” winds are specific to mountain ranges in which cold, moist air ascends the windward slope, condenses, and adiabatically descends the lee slope as a warm, dry wind. Regional names include foehn in the Alps, Santa Ana in Southern California, and chinook in the Rocky Mountains.

Measurement

Wind is typically characterized by its speed and direction. Surface wind speed is frequently measured with anemometers that are colocated with other meteorological instruments at 10 m above the bed. Four-cup anemometers were invented in 1846 by John Thomas Romney Robinson. Modern-day cup anemometers have three cups, as the reduction in cup number allows the instrument to respond faster to changing wind speeds. If fine spatial and temporal resolution is required, hot wire and thermal anemometers are used to sample at rates in excess of 25 hertz, with minimal disruption to the wind field. Sonic anemometers measure the horizontal, vertical, and lateral flow components and are needed to study turbulence. During fine-scale and/or turbulence studies, wind velocity is often measured at multiple elevations above the ground. Wind velocity logarithmically increases from the surface, according to the “law of the wall” equation developed by Theodore von Kármán in the early 20th century. Since the 1990s, global ocean surface wind speeds have been measured from space using radar scatterometers. Jet streams and other upper-level winds are measured with weather balloons.

Units frequently used to represent wind speeds are meters per second (m/s), kilometers per hour (km/hr.), nautical miles per hour (knot), miles per hour (mph), and feet per second (ft./s). One m/s is equivalent to 3.6 km/hr., 1.9 knot, 2.2 mph, and 3.3 ft./s. The windiest place on Earth is George V, Antarctica, where speeds typically exceed 325 km/hr. Dodge City, Kansas, is the windiest city in the United States (22 km/hr.)—the “windy city,” Chicago, Illinois, only averages 16 km/hr. Jet

stream velocities accelerate during winter, averaging approximately 150 km/hr., compared with summer averages of about 75 km/hr.

The Beaufort wind scale (after Sir Francis Beaufort) originated as a method for mariners to estimate wind speed from observations of the sea and is still used to categorize wind speeds. The modern scale has 12 classes; the upper extent classifies all winds greater than 73 mph (117 km/hr.).

Wind direction is most frequently measured 10 m above the surface with a wind vane. Winds are named according to the source direction, employing the 16-principle compass bearings.

The wind chill factor, or a measurement of the effect of cold temperature and wind velocity on humans, is predicted and reported by the U.S. Weather Service. It is an estimate of how the temperature “feels” to humans.

Importance

Wind is one example of a geomorphic agent of change. Aeolian-formed landforms are estimated to cover 20% to 25% of Earth’s land surface. Wind speed and duration and fetch length influence the formation of wind, or gravity, waves (1- to 30-s periods). Wind-generated waves are created from the tangential forces created when wind travels over water. Gravitational forces act in a restorative capacity and oppose wave growth. Present-day wind on Mars is evidenced by aeolian ripples superimposed on dunes, sediment accumulation on the lee side of protruding rocks, and yardangs.

High-velocity winds may have a significant impact on human life and the environment. Mid-latitude storms form when warm tropical and cold polar air masses interact. The warm air jet-tions vertically and cyclonically. During their most organized stage (cyclogenesis), these storms typically comprise two fronts—warm and cold—rotating counterclockwise (Northern Hemisphere) and clockwise (Southern Hemisphere) about a low-pressure system. Cold fronts produce various types of precipitation, including rain, hail, snow, and sleet.

Tropical cyclones comprise a low-pressure center with winds rotating around the eye in the same direction as observed with midlatitude

cyclones and have sustained winds exceeding 115 km/hr. The storms are hurricanes in the northern Atlantic and eastern North Pacific, typhoons in the western North Pacific, cyclones in India and Australia, and buguios in the Philippines. Storms are hundreds of kilometers wide; the eye is approximately tens of kilometers in diameter. Tropical cyclones form when upper-level winds diverge and the air aloft is leaving faster than the surface air is entering. Storms are fueled by the transfer of sensible and latent heat from tropical ocean waters to the atmosphere; therefore, storms dramatically lose strength at landfall. The Saffir-Simpson Scale ranks hurricane wind intensity from 1 to 5 and is used to estimate potential property damage and coastal flooding. Since hurricanes began to be categorized using this scale, three Category 5 tropical cyclones have made landfall in the United States: Labor Day Hurricane (1935, Florida Keys), Hurricane Camille (1969, Mississippi coast), and Hurricane Andrew (1992, Homestead, Florida); however, Hurricane Katrina (2005, Mississippi and Louisiana coasts) is the most devastating storm to date and affected the land as a Category 3 cyclone. It is believed that the changing climate will increase the frequency of intense tropical storms.

Tornadoes and “dust devils” are vertical columns of circulating air. The latter is smaller spatially, ranging from 1- to 10-m wide and from 1- to 1,000-m high, and is formed when hot surface air rises, giving way to cooler, lower-pressure air. Tornadoes vary dramatically in size; however, in the United States, a conservative average surface width is hundreds of meters, with an average ground path length of approximately 10 km. Tornadoes are classified according to the Enhanced Fujita Scale (since 2007), ranging from EF0 to EF5. EF1 and EF2 make up approximately 85% of all U.S. tornadoes, with wind speeds less than 178 km/hr. Tornadoes with wind speeds exceeding 322 km/hr. (EF5) are rare; only two have been reported—in Greensburg, Kansas (May 4, 2007) and concentrated around Parkersburg, Iowa (May 25, 2008). There has been a dramatic increase in reported tornado activity since the 1940s; however, much of that increase is due to improved detection capabilities.

Average wind speeds can severely affect the human and natural environment. The Dust Bowl

in the Western United States was caused from seasonal winds eroding the agriculturally damaged soil, turned into dust. The airborne particulates had a significant impact on the respiratory systems of humans and animals across the United States.

Wind influenced global ship-borne expeditions, and thus the colonization of the New World. Modern-day transportation is still influenced by wind, including shipping vessels, commercial and private air traffic, and space flight. Airports, for example, are designed to accommodate the regional prevailing wind direction because aircraft always depart and land into the wind.

Wind-generated power is an alternative to fossil fuels. Power is generated from a turbine or a wind farm, comprising a group of turbines. Consistent wind speeds exceeding 16 km/hr. are ideal. Wind turbines are typically located on land in mountainous regions, near the coast, or offshore, the latter presently exclusive to Europe. Wind farms have relatively minor environmental impacts but are damaging to migratory species and local aesthetics, and they increase noise and light pollution.

WIND ENERGY

The wind is a natural energy resource that has been used by humans on a modest scale for hundreds of years. Recently, however, concerns about climate change and diminishing reserves of fossil fuels have resulted in an increasing interest in wind as a major contributor to future energy needs. This renewed interest has not been without controversy, and major obstacles remain to realizing the full potential of wind as a modern energy resource. Doing so will require significant modifications to our energy infrastructure. It may also require some unpleasant compromises and difficult decisions about how we value Earth's resources.

The Natural Phenomenon

Earth's winds are generated by seasonal and geographic variations in planetary heating, resulting in the formation of weather systems that redistribute heat around the globe. Wind can be used to perform work because air has mass, and thus, as it moves it has kinetic energy. The amount of kinetic energy (KE) possessed by a given volume of air with mass (M) and velocity (V) is described by the relationship $KE = 0.5MV^2$.

Earth's winds are dissipated by their interaction with the planet's surface, which acts as a source of friction. Because of friction, winds on our planet are typically stronger and more consistent the higher one travels into the atmosphere. For the same reason, near-surface winds are typically higher in areas where there are few surface obstructions, such as on the ocean, treeless plains, and glacial plateaus. The twin influences of altitude and terrain can sometimes result in dramatic spatial variations in average wind speed over short distances. In addition, the wind speed varies considerably over time, so wind is considered an *intermittent* energy resource.

Generating Electricity From Wind

Although in the past wind energy was used to propel sailing ships, pump water, and grind grain,

it is currently used almost exclusively to generate electric power. Turbines used to generate electricity come in many shapes and sizes. The most common modern design uses three vertically oriented blades to drive a shaft oriented in the horizontal direction, usually termed a *three-blade, horizontal-axis turbine*. Other varieties exist (e.g., different types of vertical-axis turbines) but are comparatively rare. Modern wind turbines are typically measured by their ability to generate electric power, termed *rated capacity*. The rated capacity is the maximum amount of power that the turbine can instantaneously produce under ideal conditions. Modern turbines range in power output from several hundred watts (W) to several megawatts (MW). One MW of electricity-generating capacity can serve 200 to 300 average homes. Today, the nation with the largest installation and rated capacity of wind turbines, or "wind farms," is Germany, with the United States and Spain a distant second and third.

The capacity of a wind turbine is determined to a large degree by the length of its blades and the area they sweep, termed the *swept area* (A). The power (P) in the area swept by the blades is determined by the relationship $P = 0.5\rho AV^3$, where ρ equals the density of air (in kilograms per cubic meter, kg/m^3) at sea level. To arrive at the actual rated capacity of a wind turbine, additional coefficients must be added to describe the efficiency of the turbine. Turbines used for commercial power generation often top 400 feet from the base of the tower to the tip of the blades, allowing for longer blades and a larger swept area as well as giving them access to stronger, less turbulent winds away from the ground.

Advantages

The theoretical potential of wind energy is one reason why it is seen as an attractive energy resource. The amount of energy contained in Earth's winds is enormous on the human scale. Some estimates indicate that in theory there is enough wind energy potential in the United States to serve *all* the country's current energy consumption, not just electricity usage. Areas of high wind energy potential are widespread throughout the world, although areas of high potential

Wind turbines on Royd Moor above Penistone in South Yorkshire, England. Completed in 1993, the wind farm has 13 turbines that incorporate features intended to reduce noise.

Source: © Can Stock Photo Inc.

are frequently concentrated in certain regions such as the U.S. Great Plains.

Complementing its widespread availability and potential, wind energy is attractive because it is a renewable resource and because it does not produce any of the harmful emissions associated with fossil fuel electricity generation, including carbon dioxide associated with climate change. A more recently realized benefit is that the cost of wind-generated electricity is generally lower than the cost of other renewable alternatives. In fact, wind even compares well with some types of fossil fuel in electricity generation, particularly natural gas.

Drawbacks

A chief drawback of using wind to generate electricity is that it is an uncontrollable, intermittent resource. Electricity cannot be effectively stored for long, so supply must balance demand at all times to keep the electric grid functioning. In some cases, wind power may not be available when it is needed, creating the need for expensive

backup generation. Compounding this problem, electricity demand is typically highest on hot summer afternoons, which often does not coincide with peaks in wind power.

A further disadvantage of wind power is that wind farms must be sited in areas with good wind resources to be effective. Unfortunately, more often than not such areas are long distances away from the population centers where the electricity is needed. Developing electricity transmission infrastructure to transport wind power is a long and expensive process. An additional drawback is that utility-scale wind turbines are large, highly visible, and intrusive. Some people consider them ugly and argue that they destroy the beauty of treasured landscapes. Others believe that they pose a threat to wildlife, particularly birds and bats. Both these issues are often hotly debated in areas where wind farms are proposed.

WIND EROSION

From the sand seas of the Sahara to the loess plateau of China, to the yardang fields of Iraq and the dune fields of the Lençóis Maranhenses in Brazil, wind erosion has led to the development of distinctive and often dramatic landscapes. Many of the most recognizable of these landscapes, the sand seas and dunes, for example, are the product of the deposition of wind-eroded material. Wind erosion has also shaped landforms on Mars. Although wind does not have the erosive power of flowing water or ice, its pervasiveness compensates for that lack of force. It has been estimated that as much as a third of the land area of the Earth is susceptible to wind erosion (with the continents of Asia and Africa most at risk). Catastrophic wind erosion of soils in the Great Plains of the United States during the Dust Bowl era of the 1930s caused the infamous “black blizzard” dust storms and also led to the creation of the U.S. Department of Agriculture and the (then) Soil Conservation Service. This discussion of wind erosion is organized around four central themes: (1) erosion processes, (2) transport processes, (3) erosional landforms, and (4) wind erosion hazards.

Erosion Processes

Wind causes erosion mainly through two mechanisms: deflation and abrasion. Deflation is the

direct removal of unconsolidated sediments from a surface. Abrasion occurs when the wind is carrying a sediment load that can work on and reshape an otherwise resistant surface. Once materials have been eroded, they are then subject to transportation by the wind and deposition in another location.

Deflation

The wind is able to deflate materials when the force it exerts on a surface exceeds the resisting forces acting to stabilize the particles. For a dry sand surface, there is a physics-based relationship that balances the resisting force of gravity against the driving force of the wind. The state where the resisting and driving forces are in balance is termed the *threshold condition*. Quantification of the threshold state is fundamental to predicting wind erosion and is simplest when sediments are cohesion-less. When they are not, the process becomes much more complicated. If the sand is wet, for example, then there is an added resisting force caused by surface tension binding the grains. The presence of salt crusts or algae will also increase the necessary threshold wind speed.

For dust particles (i.e., silts and clays), establishing the threshold condition is more complicated. Such particles may be bound to each other by electrostatic forces, for example. For soils, the initiation of motion also depends on the characteristics of clods, such as size, organic content, and moisture content. For agricultural soils, there are also larger-scale controls such as cultivation practices or the presence of wind shelter belts. The Wind Erosion Prediction System is a model developed to account for these and other factors, based on simulation of field conditions such as particle size, clod processes, moisture, and organic content; wind speed and threshold conditions; and management practices, among other things.

Abrasion

Aeolian abrasion is caused by the impact of wind-borne sand or dust particles on a lithified or cohesive surface. Abrasion occurs when the resisting force, in this case, the strength of the surface material, is less than that imparted by the impact of grains. Saltating sand grains may affect igneous

or metamorphic rocks with enough force to generate microscopic fractures so that small pieces of the parent rock become susceptible to chipping away—a natural sand-blasting process. Abrasion of sedimentary rocks is more apt to occur as a result of wearing away of the cementing materials that bond individual grains, thus releasing those grains from their matrix. The rate of abrasion is a function of the cube of wind speed and the size and availability of grains for transport. Abrasion is most common in dry windy climates, where there is minimal vegetation to stabilize surfaces and reduce surface wind speeds. For these reasons, abrasion is an exceptionally active process on Mars, where wind speeds are quite high and there is an abundance of unconsolidated sediment and no vegetation.

Transport Processes

Once particles begin to move, their transport rate, Q , is a function of the cube of wind speed, the threshold condition, and the size and density of the grains. Once the shear velocity exceeds the threshold value, transport increases rapidly with additional increases in wind speed. The blowing sediments move in four ways: creep, reptation, saltation, or suspension. Creep refers to the movement of particles while in almost constant contact with the surface—by rolling, for example. Reptation is the sporadic movement of grains in short hops close to the surface caused by the impacts of other grains. Grains saltate by bouncing across the surface in trajectories that are long compared with their height and with heights that are great compared with those of reptation. Saltating particles are only occasionally in contact with the surface. Most aeolian sand transport is via the mode of saltation. Suspension occurs when particles travel mainly without contacting the surface, supported in the air by turbulent motions that exceed the gravity force. Most fine particles (dust) are transported via suspension.

For a given location on a sediment surface, erosion will occur if the quantity of sediments being removed downwind exceeds the quantity being received from upwind, regardless of the wind speed. Variations in transport rates are caused by changes in sediment availability or changes in wind speed. Changes in sediment availability are

associated with surface conditions. If the surface upwind of a location has no sediments or the transport potential of sediments is limited by cohesion, then the entire transport demand must be fed by localized erosion. More subtle changes in sediment supply are caused by variations in grain size (because of their influence on threshold shear velocity) or changes in surface slope—it is harder to move grains uphill than downhill.

Changes in the near-surface wind speed are caused by changes in surface roughness, such as those caused by the development of ripples, or by the presence of obstructions such as vegetation. Dense stands of dune grasses can stop sand transport because local wind speeds can be reduced to zero. At larger scales, changes in the wind regime may result from topographical control of wind speeds and directions or changing weather patterns. Winds are accelerated, decelerated, and steered around mountain ranges and through valleys, for example. These controls may effect the movement of either sand or dust.

Landforms of Erosion

Erosional landforms are of two general types: (1) those associated with deflation and (2) those associated with abrasion. In the former case the resulting forms are depressions, whereas in the latter case the resulting forms may stand above the surrounding landscape.

Deflation Forms

Blowouts and pans are the two most common erosional forms caused by deflation. Blowouts are scour forms that occur in vegetated coastal dune systems, usually in trough or saucer configurations. Trough blowouts occur in foredunes when the wind erodes a gap through the dune (see foredune system photo). Trough blowouts are frequently associated with the development of parabolic dunes, as the blowout becomes a pathway for windblown sand to pass through the dune. Such blowouts may deflate until erosion is prevented because the sand surface becomes armored by lag deposits of coarse sediments or shells or because the water table is reached. Saucer blowouts occur in back dune systems where there is localized failure of vegetation, which

The foredune system at Guadalupe, California, is densely dissected by trough blowouts. The area depicted is approximately 0.2 square km.

Source: Google Earth.

exposes the underlying sand to the wind. Saucer blowouts are depressions that are elongated along the axis of the dominant wind transport direction, but where winds are highly variable, these blowouts become nearly circular in outline. Erosion of these blowouts is also limited by armored surfaces or the water table.

Pans are shallow, wind-eroded depressions with maximum dimensions of tens of meters to

tens of kilometers. They occur in arid to semi-arid environments, where the sparse vegetation leaves much of the surface exposed to erosional winds. Large pans tend to form in the bottom of enclosed drainage basins. Their origins are often complex, involving the interplay among geological structure, internal drainage patterns, weathering, pedogenesis, climate, and wind. In cases where the role of wind is central to pan formation,

A pan field from Western Australia. The area depicted is approximately 40 square km.

Source: Google Earth.

there are usually downwind sand dunes or lunettes (dunes where the clay content of the sediments exceeds 20%). Pans of this type are found in the Basin and Range provinces of the Western United States; Western Australia and New South Wales, Australia; Northern and Southern Africa; Manchuria; the pampas of Argentina; and Mongolia, for example. Many pans are seasonally flooded, and if they are large enough, their shorelines are subject to erosion and reworking by wind waves. Where wind waves modify pans substantially, the long axis of the pan tends to be perpendicular to the dominant wind direction.

Small pans are formed by deflation, usually of soils. Deflation pans occur in sets, often in large numbers densely distributed on the surface,

where they may be the most conspicuous landscape element—especially when they are flooded or lined with saline soils (see Western Australia photo). Fields of small pans occur in Australia, the U.S. Great Plains, Botswana, South Africa, and China, for example.

Deflation surfaces develop when wind removes fine grains from a particle size distribution, leaving behind a lag deposit, or armoring, of sediments that are too large to be blown away, or where crusting, as by salts, occurs to stabilize a surface. In coastal environments, deflation surfaces form on washover fans. Such surfaces may form on exposed glacial till surfaces, on or adjacent to dry lake beds or streams. Some desert pavements may be caused by deflation, although other processes may be active as well. Extensive

armored surfaces are called hammada or reg, especially in North Africa, Australia, and Asia.

Abrasion Forms

Erosion of cohesive or lithified surfaces creates forms of two general types: ventifacts or yardangs. Ventifacts (“wind made”) are any of several characteristic wind abrasion features formed on bedrock outcrops or on individual stones. The main shapes associated with ventifacts are facets and flutes, and there are several minor forms, including pits and sills. The classic ventifact shape is the dreikanter—a stone with three facets. Each facet is believed to have formed at right angles to the dominant wind direction, with multifaceted ventifacts resulting from the rotation of the stones, the occurrence of abrading winds from more than one direction, or abrasion caused by secondary flows. Flutes are channelized scours that develop in parallel sets oriented parallel to

the dominant wind direction. Their formation is attributed to abrasive (probably dust-carrying) vortices. Ventifact characteristics such as orientation are used in the reconstruction and interpretation of paleowind climates. Ventifacts have been used to reconstruct wind regimes on Mars.

Yardangs (see Mars photo) are streamlined, wind-sculpted forms that vary in length from less than a meter (m) to tens of kilometers (km) and are 4 to 10 times as long as they are wide. They are oriented parallel to the dominant wind direction. Sculpting of yardangs by wind action is usually confined to the lowest 1 or 2 m of the exposed surfaces, whereas a suite of other subaerial processes may operate on the higher slopes of the landform. Most yardangs are eroded from cohesive sediments such as silts, clays, or chalks, but they may also form in sandstone or limestone. The local relief increases as material is weathered, abraded, and blown away from the depressions that separate individual yardangs.

Yardangs usually occur in sets, or fields, because their development is controlled by regional wind conditions and local geology. Fields of megayardangs (with individual lengths exceeding 1 km) may cover thousands of square kilometers and are found mainly in hyperarid climate regions such as Namibia, Chile and Peru, interior China, Chad, the Middle East, and North Africa. Megayardang fields are also common on Mars.

Wind Erosion Hazards

Hazards as a direct result of wind erosion include loss of agricultural soils, migration of sands over infrastructure or valued resources, increased respiratory disease, and poor visibility, to name a few. The loss of agricultural soils is a global problem affecting food security, especially in marginal, semiarid environments such as the Sahel. Problems may arise because of the direct loss of agricultural productivity caused by erosion of topsoil or at downwind locations because of the indirect impact of deposition of sediments on crops or in waterways, for example, or by the transport of toxic materials such as pesticides and herbicides. It has been estimated that the magnitude of the offsite costs of blowing dust may exceed 40 times that of the onsite costs.

Blowing sand and migrating dunes have buried or threatened settlements in environments as disparate as Ireland, Denmark, the Western United States, Brazil, and North and South Africa. In some cases, this led to complete abandonment of sites. There is a similar threat to roads, railroads, and agricultural lands in many of these places and also in others, such as the Takla Makan of China, Australia, and New Zealand. Atmospheric dust can produce human and animal health hazards at a great distance from its source, especially respiratory diseases such as asthma, emphysema, and lung cancer. Blowing dust can reduce visibility catastrophically, leading to traffic accidents. In less dramatic cases, the reduced visibility requires daytime illumination of street light systems.

WINE, GEOGRAPHY OF

An excellent way to comprehend a region's geography is to study its wine. Wine production is inextricably intertwined with the physical, cultural, and economic geography of a region; in essence, to drink a wine is to taste its geography. So widespread is the influence of wine in geography that a review of the geographical literature and an inspection of papers at professional meetings show that most subfields of geography are represented. Up-to-date references are available at the Association of American Geographers' Wine Specialty Group Web site www.geographyofwine.org.

Wine has been a research topic in geography since the ancient Greek and Roman geographers. Historical geographers pinpoint the home of the wine grape, *Vitis vinifera*, as southwest Asia, and its diffusion and history have been documented in works by Sauer, Unwin, and McGovern. *Vitis*

Vineyards in the Chianti region of Tuscany, Italy

vinifera is a remarkably adaptable plant with many subvarieties, each with a preferred environment, providing geographers with a fertile research opportunity.

The geographical nature of wine can be appreciated by looking at wine labels. The most prominent identifier is the source region of the wine—for example, Bordeaux, Burgundy, Champagne, Barolo, Rioja, Chianti, Brunello di Montalcino, and Valpolicella. European wines are named by the geographic region of production and not by the grape variety. Most Americans recognize the name Champagne, but few know that their favorite bubbly can only be produced in one small region of France or that it is made from Pinot Noir, Pinot Munier, and/or Chardonnay grapes. Over hundreds of years of experimentation, European winemakers have identified the best grapes in a particular region. The grape variety is not mentioned on the label; they just assume that one knows the contents by the geographical name. Red wine from Burgundy is made from Pinot Noir, Chianti from Sangiovese, and Barolo from Nebbiolo. New World wineries have little history and are still experimenting; therefore, the grape variety is prominently displayed.

The French belief that geography has a great impact on wine is epitomized by their use of the word *terroir* to define the sum total of all physical and cultural aspects that give a wine its characteristics. The concept of *terroir* dictates that geography gives wine a sense of place and that the wine is unique from wine produced elsewhere. *Terroir* is a powerful geographical concept because it synthesizes the spatial elements of the natural environment with the socioeconomic ones.

There are many variables influencing *terroir* or the geography of wine. Of prime importance are the physical variables, including climate, microclimate, air drainage, solar prospect, water drainage, geology, topography, altitude, and soil conditions. There are also socioeconomic factors, including grape-growing methods, wine-producing techniques, group pressure for a specific style, the local yeast influence, the type of wood used in barrels, and even how wine pairs with local food.

The sum total of all these factors is what makes a red Burgundy unique. The same Pinot Noir grape grown in California, New York, New Zealand, or Washington will produce a wine with a different style, aroma, and taste. Not only do

the French think that a Pinot Noir from Burgundy tastes different from one produced in California, but they also believe that wines produced from different parts of a vineyard will vary because of the microgeographical conditions.

Many excellent books and articles are available on terroir. Not only does the environment influence the wine, but the wine can influence the cultural geography of an area, resulting in a wine landscape as described by geographers including Peters and Sommers. Terroir is the true essence of the geography of wine for it brings together the physical and cultural aspects that form the geographical imprint of a wine region. The idea of terroir is so accepted that several countries have a legally binding set of rules defining specific regions. The French have the Appellation d'origine contrôlée, the Italians the Denominazione di Origine Controllata, and the Americans the American Viticultural Area (AVA). There were 190 AVAs in the United States as of May 2008. Theoretically, one can taste the difference between a Cabernet Sauvignon produced in the Napa Valley and one made in the Sonoma Valley because of the uniqueness of the terroir.

Books and journal articles on the geography of wine abound. The classics are by de Blij and Unwin. Other excellent books by geographers include Peters's work on wine landscapes and several regional books by Baxevanis and Sommers. Many books are written in a geographical format by nongeographers, with the *Wine Atlas of the World* (2007) by Johnson and Robinson being an excellent reference. An especially useful geographically organized collection of books is the *Wine for Dummies* series by Ed McCarthy and Mary Ewing-Mulligan.

Geographical journals have a good selection of articles on the geography of wine. Although not a geographical journal per se, the *Journal of Wine Research* has many articles on geography and terroir. Several recent articles highlight weather and climate (e.g., the Niagara Peninsula lake effect, global warming). Other articles highlight the use of remote sensing and using geographic information systems (GIS) to analyze the best places to plant vineyards, how to protect vineyards from insect pests, and how to assess their productivity.

In conclusion, whether it is regional analysis, comparative studies, terroir, climate, GIS analysis,

diffusion studies, economic analysis, or studying cultural winescapes, the geographer is uniquely equipped to study the geography of wine.

WINE TERROIR

Terroir is a concept introduced by French wine-makers to portray the characteristics of the place where grapes are grown that help define a wine's aroma, flavor, and other components sensed by the consumer. A wine that reflects its geographic origin thus expresses its terroir. The terroir is essentially the physical geography of the vineyard

Vineyard in the Constantia region of Cape Winelands in South Africa

Source: Don Bayley/iStockphoto.

as a function of the ecological and physiological response of the grapevine to its site, including the climate, geology, soil, and topographic factors that may influence vine growth, rooting, crop load, and fruit ripening. Wine growers around the world understand the importance of terroir and how it is expressed in the wines, choosing to cultivate specific wine varieties on sites that will produce the best wines. Through careful wine tasting, consumers learn to recognize wines by their origin and detect this sense of place or appellation of origin in tastings. Many winemakers choose to let the essence of terroir shine through in their wines versus masking these characteristics through winemaking practices.

Physical Geography and Wine Growing

The physical geography of an agricultural field, and in this case a vineyard in reference to wine grapes, exerts important controls on viticulture, with subtle differences in climate, geology, soil, and topography reflected in the wines produced from grapes grown at different sites. These site characteristics may act in a singular fashion or in tandem, such that grapes produced in adjacent vineyards on different soils, but with the

same climate, produce wines with different characteristics, or soil and climate may act mutually to change the character of wine grapes along a gradient up valley, where both climates and soils change.

Terroir is a concept introduced by the French in their Appellation d'origine contrôlée (AOC) system and is now used by winemakers worldwide to explain the essence of place as a function of the physical geography of the vineyard where the grapes for any particular wine are grown. French viticulturalists have shown that distinct differences in wine-growing districts and vineyards in Bordeaux, for example, produce very different wines as one proceeds inland up the Garonne and Dordogne rivers across river and glaciofluvial landforms and soils of different types and ages. Winegrowers in other regions of the world, including California, New Zealand, South Africa, and Germany, have used this same concept of vineyard geography to develop vineyards and produce wines best suited to the site. Agencies that regulate the naming of agricultural regions and the labeling of wines have established similar geographically based appellation of origin systems in various countries, such as the American Viticultural Areas program in the United States.

Because of the impact of vineyard geography on fruit composition, and subsequently on the flavor and other characteristics of the wine, vintners have long been interested in the effects of climate and soils on wine. Researchers have shown that climate, that is, the surface environment of the vine (canopy zone), is an important factor that affects fruit composition and wine quality and is intimately tied to the concept of the vintage (e.g., wine quality in a given year or harvest). The length of the growing season, the intensity and duration of solar radiation, temperature extremes, growing degree-day totals, precipitation events, wind speeds, and other aspects of the vineyard climate affect vine flowering, leaf canopy development, fruit set, crop load, and grape maturation. Viticulturalists can manipulate the vine canopy (through trellising, pulling leaves and shoots, cluster thinning, and other practices) to influence the microclimate of each plant, yet the regional climate effects cannot be changed (such as excessive summer heat or late-growing-season rainfall).

The soil—that is, the subsurface environment of the vine (rooting zone)—is also a primary factor affecting vine vigor and fruit composition, and the chemistry, quality, flavor, and aroma of the wine. Since it is the underground environment of the vine, it is more difficult for the viticulturalist to manipulate this part of the ecosystem, with even tillage of the soil and the addition of soil amendments not penetrating nearly to the depth that most vines root to. The fruit of the vine thus very much reflects the nature of the soil where it is grown and any related characteristics of the geology and geomorphology of that site that may influence soil texture, nutrients, water-holding capacity, and other parameters. The soil system interacts with the plant's root system to control the water, gas, and nutrient flux in the root zone to the shoots, leaves, and fruit in the grapevine's canopy. Many of the metabolic and biosynthetic processes remain poorly understood for grapevines and most other woody plants (including agricultural crop plants), thus the physiological impact of the soil on the vine remains largely unknown in a mechanistic sense.

It is encouraging that both chemical and descriptive (i.e., human sensory) evaluation of wines often allows discrimination of wines by

geographic origin, implying that the climate, geology, and soils are significant controls of grape and wine composition, even overriding whatever techniques the winemakers use in making the wine. Research has shown that unusual soils produce unusual wines and that an area that has uniform climate, geology, and soils across it (such as a single alluvial fan in a small valley or a mountain top surface) has very similar wines that can be discriminated through both descriptive analyses and multivariate ordination techniques. Doing controlled experiments, researchers have shown that *terroir* is a valid scientific concept that determines the flavor, aroma, and other characteristics of wines. In other words, place matters, and geography matters.

WISE USE MOVEMENT

The Wise Use movement was a coalition of broadly antienvironmental and antifederal organizations and political movements active in the United States from roughly the late 1980s through the late 1990s. The term *wise use* was strategically borrowed from Progressive-era conservationists, for whom it functioned very much like *sustainable development*, in both its ambiguity

and its emphasis. The Wise Use movement had three wings. The first, based in the rural West, centered on efforts by rural commodity producers to maintain their historical, privileged access to many public lands in the region for production. The second, the property rights movement, argued that governmental regulations affecting private property constituted a legal “taking” of a portion of that property, for which owners should be compensated. The third, centered in Washington, D.C., was a coordinated effort by regulated industries to repeal, weaken, or prevent many major national and international environmental laws and treaties. Each of these wings existed before and after the Wise Use movement *per se*; what distinguished the movement was their temporary alliance and commitment to a united agenda.

Wise Use was strongest in the rural West, where it was in part a cultural and political response to regional restructuring. Since 1980 or so, the rural West had seen dramatic declines in primary production industries and the concurrent growth of a service economy, rapidly increasing environmental priorities on public lands, and major demographic and political shifts. In reaction, Wise Use claimed to be a grassroots social movement, rooted in a regional culture, responding to overly intrusive outsiders. It defined itself mainly in opposition to the environmental movement and federal agencies governing land uses, which it portrayed as outsiders infringing on local rights to livelihoods and self-determination. Wise Use had a surprising amount in common with many social movements in the global South centered on resource access and control, examined in the literature of political ecology: For example, it emphasized cultural identity, local knowledge as an alternative to expert science, reinventions of community and tradition, and defenses of local claims against state authority. It was also part of a broader trend toward the neoliberalization of environmental governance.

The Wise Use movement lost cohesion in the late 1990s for three reasons. First, its three wings diverged as it became clear that pursuing their respective goals demanded different sorts of actions in different arenas. Second, groups focused on public lands realized that confrontational approaches were proving counterproductive,

and many began to seek the same ends via participation in collaborative management instead. Third, the two presidential administrations of George W. Bush (2001–2009) were highly sympathetic to Wise Use’s goals, and indeed were staffed in part by individuals with connections to it, removing participants’ motivations for an anti-federal stance.

WITTFOGEL, KARL (1896–1988)

Karl August Wittfogel was a well-known German American historian and a sinologist. Concerned primarily with humanity’s relationship with nature, his work influenced geography, anthropology, and urban studies. The environmental historian Donald Worster credits Wittfogel with pointing out that nature was not passive but formed a strong force in shaping the history of humanity. Wittfogel is also known for his early Marxist thought and his later critique of Marxism.

Wittfogel was born in Woltersdorf, Germany, and received his PhD from the University of Frankfurt in 1928. In the 1920s and 1930s, he was an active communist and an avid critic of fascism. When Hitler gained power in Germany in

1933, Wittfogel became a target of the Nazis. He was imprisoned in a concentration camp until international support prompted his release. Wittfogel moved to the United States and acquired U.S. citizenship in 1939. He taught first at Columbia University and then at the University of Washington until he retired from teaching in 1966.

Wittfogel is primarily known for his view that water played a critical role in early civilizations, states, and cities. He was especially concerned with Asian civilizations. Wittfogel explains these views in his 1956 essay "The Hydraulic Civilizations" and in his most famous work, *Oriental Despotism: A Comparative Study of Total Power*, published in 1957. One central point of Wittfogel's hydraulic civilization thesis is that arid and semiarid societies required tremendous amounts of control and stern management of water resources. Wittfogel believed that water was a key resource for civilizations. Water was needed for irrigation and was vital for agriculture in arid and semiarid regions and often required large engineering projects that were built with forced labor. Wittfogel believed that this factor was especially important in the early development of Asian civilizations. He notes that other resources, such as soil and air, are as important to agriculture as water, but water differs in one principal way. Water can be stored. In Wittfogel's opinion, the control of water resources was such an important factor in the survival and development of Asian civilizations that he refers to them as hydraulic civilizations. Wittfogel believed that the control over water gave governments enormous power over people. According to Wittfogel, the rulers of civilizations in arid and semiarid areas eventually acquired a tremendous amount of control. Governments ruled strictly and monopolized their economies through "hydraulic government." The word *despotism* in the title of his well-known work refers to this harsh control over the lives of masses of people. Some, such as Neil Smith, view his concern with Asian despotism as a slightly veiled critique of communism.

WOOD, DENIS (1945–)

Denis Wood is an artist, writer, cartographer, psychogeographer, and independent scholar. A former professor of design at North Carolina State University, Wood writes extensively on the nature of maps, mapping, and mapmaking processes. He has helped establish the subdisciplinary field of critical cartography, refining and extending J. B. (Brian) Harley's questioning of the objective neutrality of maps. Wood explores the social and political implications of mapmaking through playfully antagonistic prose, polemically undermining the authority of Western scientific cartography. He develops a theoretically rigorous critique of the power of maps, drawing on poststructural thinkers Michel Foucault and Jacques Derrida, the linguist Ferdinand de Saussure, the literary theorist and semiotician Roland Barthes, and the developmental theorist Jean Piaget. Wood is responsible for broadening the definition of maps as cultural products inherently imbued with power.

Eschewing the criterion of accuracy, Wood reads maps as narrative texts and members of a broad family of representations alongside landscape portraits and detective stories. After early research studying experimental maps, mental maps, and map literacy acquisition, Wood turned to semiotics to cast maps as sign systems coproduced with specific sociohistorical contexts. Maps are inherently subjective propositions that work

within a discursive system of coded representations to link an imagined territory with associated phenomena. A false distinction between maps and other forms of representation limits the creative, emotional potential of maps gained through a narrative understanding.

Wood relentlessly attacks cartographers for their legitimization of scientific maps. The professionalization of mapping masks political interests under pretenses of unbiased, distanced neutrality. Through claims to objectivity, maps portend to represent a world of facts as they really are rather than as purposively selective fictions that create the world as much as they closely resemble it. The presupposition of accuracy obscures the politics embedded within maps and empowers them as weapons of domination, reproducing society and legitimizing the status quo.

While modern cartography has served the interests of the State and the dominant elite, counter-mapping practices also employ the power of maps for resistance. Wood calls for the death of cartography and the return of mapping to the status of a universal birthright of humanity. His recent collaborative work with John Krygier assists nonprofessionals with map design through visually rich narratives, graphical guides, and a Web site dedicated to do-it-yourself (DIY) cartography.

WOODFUEL

Wood and charcoal provide the major energy resources for most residents of developing countries, especially for cooking and heating. To these people, the real energy crisis is the disappearing sources of inexpensive or free wood for fuel, along with deforestation. The persistence of mass poverty in regions such as sub-Saharan Africa limits access to these resources. Pitfalls in energy sustainability erode gains in the potential for human development and environmental sustenance.

Access to adequate and appropriate energy resources has implications for the economic, social, and ecological dimensions of both local and global development. Energy is a necessary requirement for sustainable development. The commercial energy sector has powered recent gains in global economic growth and has been the main driver in the globalization of the world economy. Nations with a high proportion of modern and conventional fuels in their energy mix, such as those in the global North, tend to have highly advanced economies. Conversely, nations in the South, with a high proportion of traditional fuels, have generally faced complex human development challenges in providing livelihoods and environmental quality. The relationship between energy and economic development is not necessarily direct; however, energy is a critical input in the development framework.

To sustain the existing expanding economies and to accommodate new and potentially high-demand entrants from the developing world, energy supplies need to expand. While global energy supplies are experiencing relatively low or even flattening growth rates, demand levels are escalating. Recent aggressive participation in global energy markets by giant economies with hitherto low demand streams, such as China and India, could

exacerbate this situation. Conservation measures have not made up for the gaps in energy supply. This trend could make many other countries less competitive in global markets for reasonably priced energy resources. While international markets have a robust capacity to balance energy supply and demand levels, adverse supply constraints could stretch the resilience of the system beyond the normal efficient allocation mechanisms. The looming threat of global climate change adds a new urgency for policymakers to broaden the range of energy strategies to include sources that were previously discounted, including woodfuel.

Woodfuel has been perceived to play a minimal role in models of modern socioeconomic development, but this is simply a world economic view. Regionally, wood caters to the needs of the majority of the rural population in developing nations. The sizable urban population there also depends on woodfuel, especially charcoal; and electric power supplies are erratic, overpriced, and nonexistent in large sections of the ever-expanding spontaneous settlements. Furthermore, cheap alternatives such as liquefied petroleum gas are not easily accessible, and substandard equipment and inadequate safeguards make them potential hazards in the cramped living spaces of slums.

In the developed world, only a relatively small amount of both value-added and raw wood is used to generate electricity. It is still used for limited-space heating in the northern regions and may even provide fuel for gourmet cooking. Wood is by no means the primary source of energy, and the vast majority of the population does not use it directly since cheap commercial fuels are readily available.

For the majority of the world's rural population, especially in sub-Saharan Africa, wood of all types and forms is the primary fuel source. This

Three women in a village in Maharashtra, India, carry wood logs to use as fuel for cooking.

Source: iStockphoto.

includes high-oil-producing countries such as Nigeria, Angola, and Gabon. Rural sub-Saharan Africa has an estimated electrification rate of only 7.5%, and therefore, an estimated 70% to 90% of the population depends on biomass fuels, principally wood. South Asia, with the next lowest rate, had an electrification rate of 30.1% in 2005. The World Energy Council noted that while Africa has nearly 13% of the world's population, its share of the world's primary energy consumption is only 3%. These facts and similar others demonstrate a real need for expanded access to the commercial energy sector through development, as well as policy, research, and technological

attention to woodfuel, which is often readily available.

Considered inefficient and often unsustainable, woodfuel has nonetheless enabled the poor countries of the world to survive socioeconomically and ecologically. The energy budgets of most developing countries confirm this. In effect, woodfuel has saved these cash-starved economies trillions of dollars in deferred energy imports over the years. Such savings have benefited other areas of national needs such as education, health care, and general infrastructure. Meanwhile, the low participation of these developing countries allowed many of the energy-intensive economies to buy fossil fuels at reasonable prices. The principal use of woodfuel may have prevented millions of tons of greenhouse gas emissions, compared with the dominant use of fossil fuels. This idea is supported by the fact that in the relatively sparsely populated moist forests and woodland regions, deadwood, rather than green standing biomass, is harvested for fuel. Fuel impacts on direct forest loss, in this context, is also negligible.

In all policy considerations, wood has limitations in economic growth. Inappropriate wood harvests, of course, may also trigger ecological problems such as deforestation. For all practical purposes, no modern economy can compete successfully in the global economy as it is now with raw woodfuel as its energy base.

In spite of inherent limitations, wood should be one of the alternative mainstream fuels. As global attention is drawn to the impacts of the biofuels on food prices, wood cellulose and other wood derivatives should receive scientific and technological attention. The routine use of wood in rural areas of the developing world is generally for household purposes. Research policy should focus on its calorific value, profitability for long-distance transport, smoke emissions reduction, and incentives for fuelwood farms. It is imperative that the private sector be encouraged as a necessary partner.

WORLD BANK

The World Bank (often called simply “the Bank”) is one of the Bretton Woods institutions, including the International Monetary Fund (IMF), that have their roots in the post–World War II meeting of eminent economists in Bretton Woods (New Hampshire) to discuss the rebuilding of Europe. While the Bank was to provide longer-term funds for investment in productive endeavors, the IMF was to provide short-term balance-of-payments relief.

What is often referred to as the World Bank is part of the World Bank Group, which is made up of the following five development institutions: (1) International Bank for Reconstruction and Development (IBRD), (2) International Development Association (IDA), (3) International Finance Corporation (IFC), (4) Multilateral Investment Guarantee Agency (MIGA), and (5) International Centre for Settlement of Investment Disputes (ICSID). The World Bank comprises only the IBRD and the IDA. Although the IBRD and IDA share the same staff and headquarters in Washington, D.C., each has a different focus: The IBRD assists middle-income and creditworthy poor countries, while the IDA focuses on the world’s

poorest countries (i.e., those with per capita income of less than US\$1,065 in 2008). The IBRD also has a much larger country membership and a broader mission than the IDA. It provides its client countries with loans, guarantees, and analytical and advisory services. The IBRD's financial strength enables it to borrow in capital markets at low cost and to offer clients favorable borrowing terms. The IDA provides interest-free, long-term loans, called credits, and grants to governments of the world's 82 poorest countries, which have little or no capacity to borrow on market terms. The IDA's lending is financed by contributions to the IDA from donor countries, the IBRD's net income transfers, grants from the IFC, and IDA loan repayments. IDA funds are used to finance poverty reduction programs and are allocated to countries based on anticipated "development effectiveness," and the Country Assistance Strategy is used for distributing the money within the country (Table 1).

Each of the World Bank Group institutions is owned by its member countries, which are shareholders. The Bank is supervised and directed by a 24-member Board of Governors. The voting power of the individual executive director is based on the shares of the countries they represent. The United States, Japan, Germany, France, and United Kingdom each appoint one executive director, and collectively, these five countries control 37.4% of the total votes. The president of the World Bank Group has a 5-year term and is selected by the executive directors. While this formal structure gives the impression of balance in the relative power of owner nations, in reality the United States has the greatest influence because,

as the largest contributor, it selects the president (who by tradition has always been a U.S. citizen), who is then approved by the Bank's executive directors (the managing director of the IMF has also traditionally been European). The Bank's leadership has been a source of criticism by those who argue that the developing country clients have no say in selecting its leader.

Since the establishment of the Bank in 1944, its development philosophy has gone through several transformations. The first major transformation, following the implementation of the US\$12 billion Marshall Plan for the postwar reconstruction of Western Europe, was a shift in focus to the development needs of developing countries. The second transformation, which occurred under Bank President Robert McNamara (1968–1981), shifted the focus of the Bank's loans from investments in infrastructure to broader support for development projects involving human development and economic transformation, paving the way for the Bank's initiation of structural adjustments programs (SAPs) during President Alden Clausen's (1981–1986) tenure. Implemented in the 1980s and 1990s, SAPs sought to promote economic development through trade liberalization and free market enterprise. The Bank's development philosophy was heavily criticized during its 50th anniversary, in 1994, under the slogan "50 years is enough." Moreover, the Bank was criticized for promoting and financing inequitable and unsustainable development that creates (rather than reduces) poverty and destroys the environment and for being undemocratic because it denied citizens of poor countries a role in making the major development decisions affecting their societies. These

	<i>IBRD</i>	<i>IDA</i>

criticisms led to a final transformation under James Wolfensohn's presidency (1995–2005), marked by the emergence of the “Comprehensive Development Framework” approach based on four principles: (1) a holistic long-term strategy; (2) domestic ownership, both “owning” and directing the development agenda; (3) a stronger partnership among governments, donors, civil society, the private sector, and other development stakeholders; and (4) a transparent focus on development results to ensure better poverty reduction. Today, the Bank virtually sets the global development agenda, which is currently focused on reducing poverty in developing and transition countries.

These transformations have been accompanied by a change in the composition of the Bank's staff. From a once homogeneous staff of engineers and financial analysts based only in Washington, D.C., the Bank now has a multidisciplinary and globally diverse staff, nearly 36% of whom are based in 120 offices around the world.

The Bank's dominance in setting the international development agenda stems from its enormous financial power. As the largest bank of its type, the Bank had, for instance, an administrative budget of \$2.1 billion and a combined IBRD and IDA funding commitment of \$24.7 billion in Fiscal Year 2008, easily exceeding the resources of any other international development agency. Moreover, as convener of almost all the existing consortia or consultative groups, such as the “donor” clubs, it coordinates the overall aid programs of bilateral donors as well as IMF lending to individual countries.

WORLD CITIES

A world city is a dominant place in the global economy with a disproportionately large share of the world's business functions, especially capital commanding functions, but the term dates back to at least the beginning of the 19th century, when Goethe used it to describe cities of overwhelming political and cultural importance. Within the contemporary study of geography, however, world cities are usually defined as centers with a very large proportion of command-and-control functions within the global economy (Figure 1). These are most commonly measured as large concentrations of producer services, including banking and financial services, insurance, real estate, legal services, accounting, and professional associations. World cities are also highly dependent on each other for investment and other business activities, creating a world city network. Due to increased global competition in place marketing, world city status is a desirable achievement for local planners, trying to attract outside investment or a share of the global tourism. More recently, the concept of the world city has been criticized for focusing too strongly on urban hierarchies and economic aspects and for being West-centric.

Historical Development of the Term

Although the term *world city* was used by Goethe, its meaning differed from today's conception of a world city, as it then signified a place of political and cultural importance. World city research in the contemporary study of geography focuses strongly on economic processes, although political, cultural, and social processes inform some aspects of the research. Moreover, the research is strongly shaped by disciplines other than geography, especially urban planning and sociology.

In the 20th century, Patrick Geddes also used the term *world city* in his book *Cities in Evolution*, which was published in 1915. However, the

Figure 1 Global and world cities

Source: Map created by the author. Taxonomy based on Taylor, P. J. (2005). Leading world cities: Empirical evaluations of urban nodes in multiple networks. *Urban Studies*, 42(9), 1593–1608.

British urban planner Peter Hall provided the first systematic analysis of world cities in 1966, when he published his book *The World Cities*. Hall analyzed seven cities, which were of overwhelming economic importance in the world economy at the time, but he focused on their internal structures and organization as well as national and regional roles, with relatively little attention to linkages between these world cities. Understanding world cities as part of a network of world cities did not happen until the 1980s, when researchers at the University of California, Los Angeles, among them the urban planner John Friedmann, published their hypothesis of a world city network. This reorientation in world city research was a direct response to changes in the world economy since roughly the 1970s, which saw a shift from Fordist production methods to more decentralized and flexible methods as well as a reduction in trade barriers and increased economic globalization.

A further major development in world city research came in the early 1990s, when the sociologist Saskia Sassen published *The Global City: New York, London, Tokyo*. One of the major contributions of that book was the identification of producer services as command-and-control functions in the world economy. Producer services have subsequently become and continue to be a core analytical component of world city research. The label “global city” was intended to mark a conceptual difference from “world city,” in that a global city is not merely a dominant city in the world but the processes articulated in it are truly global intercity linkages. Various rankings of a world city network were produced using producer services as an analytical cornerstone. This work was significantly advanced by the geographer Peter Taylor and the Globalization and World City (GaWC) Research Group founded in the late 1990s at Loughborough University in the United Kingdom.

World City Network

World cities are the command-and-control centers of the global economy but are not individually in a position to fulfill these command-and-control functions. Instead, they are also highly dependent on each other—that is, they not only compete for

the same business but also rely on each other in fulfilling the capital commanding functions in the global economy and thus constitute a system. The geographic distribution of cities remains of central importance for this system regardless of considerable improvements in telecommunications over the past two or three decades. The most regularly mentioned world cities at the top of the urban hierarchy, New York, London, and Tokyo, for example, are located in three distinct world regions and time zones and are thus in a position to collectively influence business in the Americas, Europe-Africa, and the Asia Pacific Region at any time, whereas one individual city could not do so. Los Angeles, Chicago, Toronto, Paris, Frankfurt, Amsterdam, Hong Kong, Singapore, and Sydney, among others, are often cited as other major world cities.

These world cities have in common that they host the largest stock exchanges and the headquarters of the world’s largest banks and other transnational producer services firms. Through these producer services or command-and-control functions, world cities fulfill core functions within the world economy. Strong links thus exist between world-systems theory, which conceptually divides countries into core, periphery and semiperiphery economies, and world city research, although the former focuses on the nation-state as the main unit of analysis and the latter on cities. World cities are often ranked into alpha, beta, gamma, and delta groups, based on the concentrations of producer services in them. Depending on changes in these concentrations, cities retain both upward and downward mobility within the system.

The Internal Structure of World Cities

The internal structure of world cities is characterized by an advanced telecommunication infrastructure, a large stock of high-end office space, a large proportion of urban amenities, spectacular architecture, and signature buildings as well as highly polarized labor markets. Moreover, the hosting of cultural festivals, sports events, and other mega events, such as the Olympics or Expos (world exhibitions), are means for cities to attract business and tourists and thus attain (or maintain) world city status.

Office space and infrastructure are essential prerequisites in attracting the offices, especially regional or global headquarters, of large transnational corporations, which give a city the status of a world city. However, cultural amenities, such as theaters, museums, concert halls, and sports arenas, are of similar importance in attracting global managerial staff and professionals to work in a city. Similarly, mega events, with their substantial global media reach, are tools for promoting a city and showcasing its attractiveness and achievements. Spectacular architecture provides an image of a city to promote it through the global media.

Partly as a result of this economic structure, world cities are characterized by a highly polarized labor market. On the one hand, a large number of professionals and managerial staff in transnational corporations receive high incomes with additional benefits, enabling them to enjoy many of the cultural amenities, while on the other hand many low-income workers struggle to find adequate housing, schooling for children, and often food. These workers often earn a minimum wage (or in case of illegal employment, below minimum wage) and find employment in low-end service jobs, such as cleaning, food services, or domestic labor. Both labor markets, high and low income, are highly international and depend on migrant workers—transnational professionals on the one hand and economic migrants on the other. The process of social polarization is also a result of post-1970s state restructuring and the reduction of social redistribution by nation-states.

Critique of the Concept

The concept of the world city has been critiqued as being West-centric and too focused on economic processes of globalization rather than on a broad cross-section of different processes, including cultural, political, and social ones. The focus on producer services privileges a narrowly defined subsection of the global economy, resulting in a focus on a small number of cities, while other important global or regional economic circuits are excluded from the analysis. Few cities that are routinely included in world city rankings are in the global South. Moreover, critics charge that through rankings of world cities, it is implicitly suggested that the cities at the top of the urban

hierarchy are the examples or standards, while other cities are the followers that should attempt to develop in the same way. Supporters of world city research point to its theoretical tradition in world-systems theory and stress that the rankings are an expression of power and influence in the world urban system rather than an indication of which cities have developed “correctly.”

WORLD COURT

The World Court is the common name for the International Court of Justice (ICJ). It is the main judicial organ of the United Nations (UN) and is headquartered at the Peace Palace in The Hague (the Netherlands). It began functioning in 1946.

The Peace Palace, also known as Vredespalais, in The Hague, the Netherlands. It houses the principal judicial body of the United Nations, the International Court of Justice, and the Permanent Court of Arbitration.

Source: Arjan de Jager/iStockphoto.

Its predecessor was the Permanent Court of International Justice (PCIJ), established in 1920 by the League of Nations. The Court's earlier roots can be traced back through The Hague Peace Conference of 1899, the Alabama Claims arbitration in 1872, and the Jay Treaty of 1794 between Britain and the United States.

Fifteen judges serve on the World Court. They are elected for 9-yr. (year) terms by the UN General Assembly and the Security Council and are eligible for reelection. Candidates must receive an absolute majority of votes in both bodies. For continuity, one third of the Court is elected every 3 yrs. Once elected, the Court's judges then elect a president and vice president. The Court's official languages are English and French.

The judges must represent the world's main forms of civilization and legal systems. No more

than one person of a single state (i.e., country) may serve concurrently as a judge. Presently, three judges are from Africa, two are from Latin American and the Caribbean, three are from Asia, five are from Western Europe and other states, and two are from Eastern Europe. Judges are not delegates of their respective countries but instead are obligated to act impartially and conscientiously. For Court cases concerning a country that does not have a judge on the Court, a country may request that an ad hoc judge from it or another country be added for such cases. Ad hoc judges also must agree to be impartial in their decision making.

The World Court has two main functions: (1) issuing advisory opinions and (2) settling contentious cases. The first centers on legal questions submitted to it by the UN's five organs and

16 specialized agencies. The second is an application of international law to settle legal disputes brought to it by countries' governments. The Court only accepts contentious cases from countries that are members of the UN and parties to the Statute of the Court or countries that accept the Court's jurisdiction. Its judgment is delivered publically and is considered final, binding, and not subject to appeal. Advisory opinions are also delivered publically but are not considered binding.

Between 1946 and mid 2008, the Court delivered 25 advisory opinions, 97 judgments, and had 12 pending contentious cases. Judgments have concerned issues such as political boundary disputes, territorial sovereignty, noninterference in the internal affairs of states, rights of passage, diplomatic relations, and human rights.

WORLD HEALTH ORGANIZATION (WHO)

The World Health Organization (WHO) was one of the earliest bodies created by the United Nations. The WHO effectively began in 1948, when its constitution came into force, and to this day it continues to spearhead global public health initiatives. Over the years, the WHO has played a key role in the organization and promotion of global programs to eradicate infectious diseases, including small pox, polio, and measles; in helping developing countries, in particular, to build

their public health care systems; and in the development of surveillance systems for and responses to highly infectious emergent diseases (e.g., Ebola).

Arguably, the WHO's greatest contribution to date is the role it has played in transforming the thinking on the development of primary health care. In 1978, the WHO organized the Primary Health Conference in Alma Ata, where WHO member countries declared,

The Conference strongly reaffirms that health, which is a state of complete physical, mental and social wellbeing, and not merely the absence of disease or infirmity, is a fundamental human right and that the attainment of the highest possible level of health is a most important worldwide social goal whose realization requires the action of many other social and economic sectors in addition to the health sector. (Alma Ata Declaration, first principle)

These words shifted the focus of research and practice away from a narrow concept of health as the absence of disease to a much broader focus on physical, mental, and social well-being; acknowledged that to understand health, research and practice must address the social and economic determinants of health; and raised health status to the level of other fundamental human rights. In other clauses, the Alma Ata Declaration sets out the responsibilities of governments to attain the goal of health and declared that the elimination of health inequalities within and between countries needed to be attained.

The WHO definition of health, its focus on the social and economic determinants of health, its advocacy of health as a right, and its goal of reducing health inequalities all found their way into the writing, research agendas, and critical debates of the 1990s among medical geographers. While medical geography continues to exist as a subfield of geography, it can be argued that the ideas that came out of the Alma Ata Conference help set the stage for the development of health geography in the latter part of the 1990s, with the take-up of key concepts from critical geography and an emphasis on place, gender, disability, population health, and the use of qualitative methods. Today, both medical and health geographers

continue to look to the WHO for its leading role in the global efforts to eradicate disease and promote health.

WORLD SUMMIT ON SUSTAINABLE DEVELOPMENT

The World Summit on Sustainable Development (WSSD), which convened in Johannesburg, South Africa, from August 26 to September 4, 2002, aimed to reaffirm and assess the progress of the multilateral commitments launched at the Rio Conference 10 years earlier. Specifically, the WSSD was designed to evaluate the progress of the Millennium Goals and Agenda 21 and to set new priorities and goals to counter global poverty and environmental degradation in the coming years. United Nations (UN) Secretary General Kofi Annan identified five priority areas for action at the Summit: (1) water and sanitation, (2) energy, (3) health, (4) agriculture, and (5) biodiversity.

The United Nations Commission on Sustainable Development served as the central organizing body of the WSSD. A 10-member steering committee (representing each region of the world) guided the process and attempted to raise political support for the summit. Four preparatory meetings were also held prior to the WSSD, three in New York City and one in Bali, Indonesia.

The WSSD is one of a series of UN global earth summits popularized since the Stockholm Summit in 1972. It was the largest summit to date, with more than 100 heads of state and an

estimated 25,000 participants (from 180 countries) representing governmental, business, and activist organizations. The WSSD differed from the previous summits in two important ways: (1) it adopted a sustainable development approach, which widened the environmental goals to include poverty alleviation, and (2) it created opportunities for greater civic engagement through the organization of a parallel stakeholder's forum conference. Stakeholders included businesses, women and children, trade unions, indigenous leaders, local representatives, farmers, and the scientific community.

Despite this new approach and the unprecedented number of attendees, the WSSD was widely criticized for failing to devise a specific time frame and funding provision for the implementation of their goals. Many blame summit fatigue for the lack of results. Others blame the increasingly neoliberal approach to global governance and the subsequent weakening of the sustainable development ideology. Furthermore, the events of September 11, 2001, and the subsequent War on Terror, along with the credit crisis of 2008, have contributed to widespread unilateral policies that prioritize military and financial security over global environmental conservation and sustainable development.

WORLD-SYSTEMS THEORY

One of the major models of how the global system of states and markets operates, world-systems theory, introduced by the sociologist Immanuel Wallerstein in the 1970s, is an enormously influential perspective on the changing structure and dynamics of the world economy. In many respects, it retains a fundamentally Marxist version of the world, one that puts production, class, uneven development, and historical context at the center.

The focus of world-systems theory is on the entire world rather than on individual nation-states. This view maintains that one cannot study the internal dynamics of countries without also examining their external ones; thus, the boundary between foreign and domestic effectively disappears. This stance notes that all regions are interconnected; that is, they never exist in isolation. Moreover, this focus notes that the growth of the West occurred *in interaction with* other parts of the world, not through its inherent internal dynamism, thus serving to oppose the widespread Eurocentrism of much of social science.

World-systems theory distinguishes between large-scale, precapitalist *world empires*, such as the Romans, Mongols, or Ottomans, all centralized political systems that appropriated the social surplus from their peripheries through the state, and the capitalist world *system*, in which there is no single political entity to rule the world but a multiplicity of entities of varying sizes and degrees of sovereignty; that is, there is a single market but multiple political centers, meaning that there is no effective control over the market. With the rise of capitalism, the primary political units shifted from

empires and city-states to nation-states. The political geography of capitalism is thus not the nation-state but the interstate system. Occasional attempts to reassert a world empire included the Hapsburgs, Napoleon, and Germany in World Wars I and II, each of which represented a temporary contraction in the world system but a permanent reconfiguration in its hierarchy of states.

Wallerstein held that the world system arose in the “long 16th century” (1450–1650) and gradually enveloped all other parts of the globe. Until the 19th century, various parts of the world *affected* one another; as they become locked into a single, worldwide division of labor, however, they became increasingly *reliant* on each other. However, recent variations of world-systems theory have extended the concept “backward” in time to include increasingly earlier social formations. For example, Andre Gunder Frank held that even Neolithic mini systems constituted a world system of sorts. Janet Abu-Lughod offered a celebrated concept of a late-13th- and early-14th-century system, which connected China, India, the Arab world, and medieval Europe via the Silk Road routes and maritime trade across the Indian Ocean but was ended by the bubonic plague. Indeed, many world-systems theorists argue that prior to the 19th century, the world economy was primarily Asian in nature.

World-systems theorists maintain that capitalism takes many forms and uses labor in different ways in different regions. In the global core, labor is predominantly waged (i.e., organized through labor markets), while in developing countries there is considerable use of nonfree labor, ranging from slavery to indentured workers to landless peasants working on plantations. Some critics of Wallerstein, particularly Robert Brenner, argue that his view prioritizes trade over the commodification of labor, leading to allegations that he is “neo-Smithian” in his worldview. World-systems theorists counter that the world economy structures places in such a way that high-valued goods are produced in the core and low-valued ones in the periphery. The search for profits through low-cost labor drives the world system forward to expand into uncharted territories.

Unlike the bifurcation between developed and less developed countries that both modernization and dependency theories advocate, in world-systems

theory there is a tripartite division among core, periphery, and semiperiphery. The core and periphery are the developed and undeveloped countries, or First and Third worlds, respectively: One is wealthy, urbanized, industrialized, and democratic, the other rural, impoverished, agriculturally based, and dominated by authoritarian governments. The semiperiphery has characteristics of both core and periphery and includes states in the upper tier of the less developed world, such as the newly industrializing countries in East Asia, Brazil, and Mexico. Core processes generate high wages, high levels of urbanization, industrialism and postindustrialism, advanced technology, and a diversified product mix. In the world periphery, the world system creates low wages, low levels of urbanization, preindustrial and industrial technology, and a simple production mix. In between are states that are part of the semiperiphery, where both sets of processes coexist to a greater or lesser degree. The theory suggests that semiperipheral countries are exploited by the core countries with regard to raw material and product flows while at the same time the peripheral regions are also exploited. However, unlike dependency theory, world-systems theory allows for some degree of mobility within the global economy: Thus, capitalism does not inevitably breed poverty; rather, its effects are contingent and historically and geographically specific. However, the possibilities of development are limited, and the development of one country via industrialization is likely to coincide with the underdevelopment of another.

World-systems theory pays particular attention to the role of a single hegemonic state that dominates the global political and economic system. The hegemon sets the rules of the game, so to speak. Hegemony exists when one core power enjoys supremacy in production, commerce, and finance and occupies a position of political leadership. The hegemonic power is the leading trading and investment country, its currency is the universal medium of exchange, and its city of primacy is generally the financial center of the world. Because of its political and military superiority, the dominant core country maintains order in the world system and imposes solutions to international conflicts that serve its self-interests. During the period of Spanish dominance in the 16th and

17th centuries, for example, mercantilism was the dominant ideology. In the 17th century, the Dutch enjoyed a brief window in which they controlled Indonesia, South Africa, Curacao, and New Amsterdam (later New York). Under the Pax Britannica of the 19th century, when Britain controlled one quarter of the Earth's surface, free trade was the norm. And since the rise to dominance of the United States, especially since World War II, neocolonialism has been the typical pattern (although during the Cold War there were two superpowers and a bifurcated world system). Consequently, hegemonic situations are characterized by periods of relative peace (e.g., the 19th century). During a power's decline from hegemony, rival core states, which can focus on capital accumulation without the burden of maintaining the political and military apparatus of supremacy, catch up and challenge the hegemonic power. Thus, in the early 20th century, Germany challenged Britain for global leadership, with catastrophically violent results.

The rise and fall of hegemonic powers is sometimes tied by world-systems theorists to long-term cycles or Konratief waves, a view that attempts to correlate upswings and downswings with changes in hegemonic status. Moreover, hegemonic powers may overextend themselves militarily, leading to an erosion of their economic base. When powers in the core have conflicts among themselves, they open opportunities both for new hegemonies and for countries on the periphery: the Napoleonic Wars of the early 19th century and World War II in the 20th century were thus openings for nationalist anticolonial movements worldwide, first in Latin America and later in Asia and Africa. World-systems theory thus allows for resistance and decolonization and notes that hegemonic power is always contested.

Geographers have been attracted to world-systems theory because of its sensitivity to spatial differences in historical experience and the ways in which it allows regions to be contextualized within a global setting. The view offers significant insights into the possibilities of development (or lack thereof), the constraints to individual actors such as nation-states or transnational corporations, the origins of war, and phenomena such as trade and economic crises. World-systems theory in various forms thus forms an integral part of

human geography and has become woven into most of the discipline's conceptualization of how the global economy and geopolitical apparatus function.

WORLD TRADE ORGANIZATION (WTO)

The World Trade Organization (WTO) is a multistate organization formed to administer a set of interlocking international agreements, which are concerned primarily with trade regulation. It also functions as a forum to negotiate changes and additions to these agreements. It officially came into existence on January 1, 1995. As of July 2008, there were 153 members, including most but not all of the world's sovereign governments. The WTO is explicitly committed to lowering trade barriers and to general economic liberalization. It plays a key role in international political economy and in contemporary geopolitics.

Most of the constituent agreements of the WTO took their present form during a series of multilateral negotiations known as the Uruguay Round, taking place from 1986 to 1994. These built on and incorporated an older set of international agreements known as GATT (General Agreement on Tariffs and Trade), dating from 1947. The Uruguay Round agreements regulate a vast sweep of international economic policy, including tariff levels, the use of nontariff trade barriers, subsidies, copyright law, trade in services, and foreign investment. In addition, trade in agriculture and textiles were deemed exceptional and were subject to separate agreements. The foundational WTO agreements also included provisions for their own alteration and augmentation in expected future negotiations. Ministerial meetings of the WTO are held about once every 2 years in different locations around the world to conduct these negotiations, the most recent being held in Hong Kong in 2005. Thus far, few changes have been made to the original agreement other than time-dependent clauses from the Uruguay

Round kicking in (e.g., the expiration of the Agreement on Textiles and Clothing in 2005).

In addition to the biannual ministerial meetings, most WTO members maintain permanent missions in Geneva, where they meet as the General Council of the WTO and staff various subcommittees. WTO headquarters in Geneva also house a permanent bureaucracy known as the Secretariat, which arranges meeting logistics, handles the circulation of documents, and dispenses implementation advice to developing country members. The highest office in the WTO is that of director general, a post currently held by Pascal Lamy, a French citizen.

In the event of a formal trade dispute between members, the General Assembly meets as the Dispute Settlement Body (DSB). The dispute settlement procedure involves an expert panel constituted specifically to evaluate and issue recommendations on each case and a permanent standing seven-member Appellate Body to hear appeals. The DSB itself has the final say as to whether or not to adopt the recommendations of the panel and the Appellate Body. In the case of a guilty verdict, the country at fault must render compensation to the winning country; if no compensation can be agreed to, then the winner of the dispute is authorized to level limited trade sanctions against the offending country. The General Assembly also meets as the Trade Review Body to conduct periodic evaluations of each member country's current economic policies.

Members of the WTO incorporate most of the world's population and economic wealth. About 40 of the world's recognized countries are not members of the WTO, notably Russia. The accession of China to the WTO in 2001 was considered a pivotal event in the growth of the WTO. Members of the WTO generally constitute sovereign states. The major exception is the European Union (EU), which is recognized as a member in itself, separate from its own member states, which also hold individual membership in the WTO. For most purposes, the 27 members of the EU choose to negotiate as a bloc. Other informal groupings of countries exist within the WTO, which often meet among themselves prior to Ministerial Meetings to hammer out a common position on specific issues. Some of the most important of these blocs include the Quad, consisting of the most powerful economies: the EU, the United

States, Japan, and Canada; the G20, consisting of about 20 (membership tends to fluctuate) of the larger developing economies, formed mainly to advocate for stronger rules against agricultural subsidies; and the G33, another coalition of developing countries formed to advocate for special and differential treatment for developing economies in the application of WTO rules.

WTO negotiations have often been contentious. Two ministerial meetings (Seattle 1999 and Cancun 2003) are notable for having broken down without producing a consensus agreement. Since Seattle, ministerial meetings have attracted large, organized protests from labor, environmental, and antineoliberal groups, among others. Since at least 2001, when the series of negotiations known as the Doha Round began, talks have been repeatedly deadlocked over the issue of agricultural subsidies, which many (mostly developing) states see as blocking their access to markets in the EU and the United States. This is part of a wider issue involving the widespread sentiment that WTO rules are biased against developing economies. Other controversial issues include the inclusion or noninclusion of labor and environmental standards in WTO rules, procedural transparency in WTO meetings, the copyrighting of genetic materials, pharmaceutical patents and the availability of life-saving drugs, special and differential treatment for developing countries, and the rights of governments to discriminate against foreign-owned companies.

WRIGHT, DAWN (1961–)

Dawn Wright is a professor in the department of geosciences and an adjunct professor in the College of Oceanic and Atmospheric Sciences at Oregon State University (OSU). Wright is a dedicated researcher, educator, and proponent of geographic concepts and spatial thinking who has made significant contributions in the fields of geographic information science (GIScience) and the coastal and marine sciences, as well as in the broader field of geography.

Wright's research includes issues of application and analysis in the use of geographic information systems (GIS) with oceanographic data, particularly data modeling, spatial analysis, and data conversion; the processing, production, visualization, and interpretation of seafloor maps; marine data modeling, metadata, ontologies, and vocabularies; and cyberinfrastructure, particularly geographic/geospatial semantic Web issues and the related use of tools such as Web portals and Web services. She is highly regarded worldwide for her work in the areas of GIScience and coastal and marine GIS.

Wright received her bachelor's degree in geology from Wheaton College (1983), master's degree in oceanography from Texas A&M (1986), and PhD in physical geography and marine geology from University of California, Santa Barbara (UCSB) (1994) under the advisement of Raymond Smith. Her research has been funded by the National Science Foundation, the National Oceanographic and Atmospheric Administration, and the U.S. Department of Agriculture and has been published in multiple books and peer-reviewed journals. One of her best-known works was as lead author of the 1997 article "Demystifying the Persistent Ambiguity of GIS as 'Tool' Versus 'Science,'" a discussion and analysis of the perception of GIS among geographers in the early 1990s. She also helped develop the ArcGIS Marine Data Model, published in 2007.

Wright teaches introductory and advanced courses in GIS, as well as seminars in geography, GIScience, and marine-related topics, and has served on many graduate student committees at OSU. In addition to research, her work is also largely defined by her service to the broader

research community. She currently serves as chair of the University Consortium on Geographic Information Science Research Committee, as an Association of American Geographers National Councillor, on the National Academies Ocean Studies Board, on the editorial boards of several journals, including *Transactions in GIS* and the *International Journal of Geographic Information Science*, and as director of the Geographic Information Science Certificate Program at OSU.

Numerous awards have recognized Wright's academic work and her contributions to science and the community. She received a 1995 National Science Foundation Faculty Early Career Development Award, was awarded a 2004 Fulbright grant to Ireland as a Senior Specialist in Information Technology, was given the Raymond C. Smith Distinguished Alumni Award in 2007 by the UCSB Department of Geography, and was selected as the 2007 U.S. Professor of the Year for the state of Oregon by the Carnegie Foundation for the Advancement of Teaching, among others. She has given invited seminars, talks, and keynote addresses at diverse conferences such as GeoTech; GIScience; Technology, Entertainment, and Design; and the Environmental Systems Research Institute Education User Conference and has published many invited articles and book chapters.

WRIGHT, JOHN KIRTLAND (1891–1969)

John Kirtland Wright, historian and geographer, spent most of his career as a professional geographer with the American Geographical Society. In his many roles at the society (including research associate, director, and, more important, editor of the society's journal, *Geographical Review*), he published more than 500 documents. Many of these were book reviews and "Notes" of one or two pages, a regular feature in the *Geographical Review*. These notes and reviews covered a diverse array of topics, including many aspects of physical, human, and regional geography, as well as geographical methods and techniques. No area in geography was omitted: Topics ranged from Ancien Régime, Antarctica, and Eratosthenes to linguistics, migration, the Pyrenees, and the Zuider Zee. It has been pointed out that his ideas and contributions are interwoven into the entire fabric of geography, into the canvas, not just splashes of paint on the surface.

Operating outside academia, many of his ideas emerged late in his career as mainstream concepts in geography, and their diversity and foresight laid foundations for intellectual structures throughout the discipline. *Aids to Geographical Research*, with Elizabeth Platt (first published in 1923, with a second edition in 1947) and other bibliographically focused resources, including the *Research Catalogue* of the AGS, were facilitators for research in the discipline. Many of his conceptual innovations deal with exploiting the relationship between history and geography. Beginning in 1925, "The History of Geography: A Point of View" was followed by "A Plea for the History of Geography" and *The Geographical Basis of European History*. This theme continued in his publications and presentations while he worked with the effective organization and presentation of statistical data; in 1937, he examined "Some Measures of Distributions." Works that followed were nonstatistical forerunners of the quantitative revolution. His 1944 paper on the "Terminology of Map Symbols" became the basis for the organization and symbolization of data on maps in academic cartography.

Cartographic concepts and processes were examined from the organization of data for mapping to the perceptual and cognitive processes of the map reader. Decades of consideration of the statistical and graphic organization of geographical information resulted in work on human nature and the impact of aesthetic feeling, imagination, and subjectivity in geography.

At the outset, given the opportunity as he began his graduate studies at Harvard, he chose not to specialize in geography, which at the time involved the study of "nature-minus-man." He decided to make his study of history geographical, which he did for half a century. He looked from a variety of perspectives at *terrae incognitae* (unknown lands), which made the use of imagination critical to geographical exploration and mapping. The results of exploration involve interpretations, modifications, and inventions, all involving aspects of the imagination. His ideas were seminal in the movement that has been called the "cognitive reformation" of American geography, involving environmental perception, cognition, and behavior. One can turn to the 1966 series of essays in *Human Nature in Geography* and find that he was ahead of the developments that would occur throughout the discipline during the 20th century.

The breadth of his perspective not only of the discipline but also of geography as a whole is embodied in geosophy, the study of geographical knowledge from any or all points of view.

WRITING

Writing is the means by which geographers have traditionally represented the physical, cultural, and social worlds as they perceive, measure, and understand them. It is a conventional tool, the use of which entails uncertainty and perceptual bias. The contingent nature of understanding conveyed through the written word is a bedrock tenet of poststructural academics, but the idea that all language is fundamentally metaphoric or “figural” is an old one, with roots in the writings of both Plato and Friedrich Nietzsche. The recognition of writing’s fraught nature in geography dates back to Immanuel Kant. Writing today is undertheorized by geographers and is largely used either unreflectively or to predictable political ends.

As Jacques Derrida indicated, writing as a tool is intrinsically imbricated in power-creating systems. Every system of symbols to represent concepts entails the embrace of a dialectical and recursive methodology that works to obscure its own mechanisms and the power relations that underlie them. While contemporary social scientists tend not to focus on the embedded nature of written understandings, the roots of the modern discipline of geography lie in a nuanced grasp of the necessarily metaphoric nature of description and depiction in conveying both measurable and perceptual aspects of particular places. Geography is crucially the expression and transmittal of understandings of places and spaces as much as it is those understandings per se.

Ralph Hall Brown played a central role in conveying the centrality to geography of not simply the physical realities of a given location but also the evolving human understanding of a place’s significance and structure. That is, he was concerned with the context of knowledge about places and how it develops over time. Recognizing that character and culture were significant influences on both knowledge and action, Brown used fiction as a lens through which to assess the state of geographical knowledge in a particular time and place. His best-known work, *Mirror for Americans*, published in 1943, is an analysis of a fictional colonial-era protagonist, whom Brown used to both humanize colonial conceptions of American geography and stress their contingent and contextual nature.

With the quantitative turn, the literary and discursive treatment of geographic perception was often considered to be insufficiently rigorous. Geography began to purport to be one of the sciences that measured rather than one of the arts that perceived. Yet many geographers—including Brown, J. Wreford Watson, Douglas Pocock, Marwyn Samuels, and especially Yi-Fu Tuan and Donald Meinig—remained committed to a conception of geographic perception that required nothing short of a literary sensibility. Tuan particularly stressed the need for geographers to cultivate, among other qualities, the empathy and insight that any good writing exhibits. Similarly, Meinig held that geographic writing had to become overtly novelistic in order to cultivate relevance and an audience.

Tuan and others promoted a focus on experiential knowledge that had linguistic implications. Just as geography moved into the social world, writing itself came to be recognized as something that entails more than just transcription and analysis of books, maps, and surveys. Both the built environment and language are vectors for individual expression and emotion and can define and shape consciousness and sensibility. Neither is merely the by-product of macroeconomic priorities or microeconomic decisions. Geography’s focus on “being in the world” led to its embrace of a necessary incompleteness—an eternally deferred final understanding that is intrinsic to writing as well. Language itself is an important power in constructing places (and, by implication,

in constructing the power that those places then exert). Spatial patterns can therefore be seen as not dependent on actual geography alone but rather as a product of the metaphors used to describe their parts.

This foregrounding of writer qualities and self-awareness found particular expression in the impressionistic works of Gunnar Olsson and the self-conscious typographic experiments of Allan Pred, which attempted to convey the feel of a place through placement and treatment of words on a page as much as through their content. A utilitarian backlash against the “New Mandarin” style was in large measure successful, as geographic writing has subsequently become essentially indistinguishable from generic social science prose.

Nevertheless, many recent conceptions of academic writing do take it as given that “objective” discourse itself has lost validity and that all expressions are socially constructed. The modernist voice that presumed a reader who was basically nonexistent as an individual, requiring only rationalist demonstration rather than any appeal to social or personal interests, has been discredited, and books or articles themselves are seen as unavoidably contingent in both content and form. Any theoretical construction is then simply spatially embedded practice, which implies that perspective is directly reliant on position, which itself is a product of social discourse.

Such an incomplete perspective is doubly endemic to geographic discourse in that it comes to grips with the relations between the structural and the experiential, or between what a place “is” and what it “is like.” Academic prose may be a useful medium through which to cogently lay out the structural aspects of social situations, but social experience itself is a distinctive phenomenon whose transmittal requires a medium that forthrightly encompasses subjectivity. Such writing is the cognitive nexus between what happens and how geographers begin to make sense of it, and “higher” thinking itself is premised on the metaphoric understanding of the world that we reflexively apply to the world’s stimuli. Moreover, contingent experience, circulated images, and stories about places are all central in comprehending the meaning of complex environments,

and they all require interpretation in addition to generalization.

Recent geographic scholarship has tended to emphasize the quality of writing, confusing it with reporting and using it as source material for interrogating social structures. Geographical approaches to literature, for example, often tend to treat it as symptomatic of society’s ills, as if it were simply another tool of a broader social hegemony or a “cultural product.” From this perspective, writers are blind to the social forces they depict, and their work as a whole is merely what the literary scholar Robert Alter refers to as a reflex of ideology. Such a perspective confuses the contents of a book and its function as literature, misreading representations of experience as experience itself.

This approach creates an impoverished discourse wherein only a certain privileged language, such as social scientific tropes, attains status as legitimate geographic argument. The limited geographic linguistic palette of the present moment is a barrier to the discipline’s ability to effect broad change. The language spoken by geographers often does not speak to common experience or to structural engagements as they are broadly understood. For example, we need only contrast the ease with which nongeographers speak of the weather to the difficulty that many geographers have in speaking with precision about place and its complications. We can speak, for example, of it “raining cats and dogs,” but similar metaphors to describe complicated landscapes (whether physical, social, or economic) do not hold the same currency. The embrace of metaphor in popular meteorology has helped foster the illusion of popular understanding and thus of popular engagement—simply put, many people feel that they have an intuitive understanding of the weather, while far fewer would claim such an understanding of any geography beyond the local.

XERISCAPING

Xeriscaping is an approach to landscape design that integrates the resource conservation objectives of communities in dry environments and water-stressed urban areas. The principal management objective of xeriscaping is to create a landscape that is water conserving and requires little or no irrigation. The term was coined by the Denver Water Department in 1981 and has been widely adopted by state, county, and city governments that promote alternatives to the common water-intensive turfgrass landscapes of North America. Xeriscaping has gained in popularity as an environmentally friendly and aesthetically pleasing alternative to such conventional landscaping. As the term has entered popular discourse, xeriscaping is increasingly used as an umbrella term for landscaping that encompasses a range of environmental objectives. These objectives extend beyond water conservation and include the reduction of chemical pesticide and fertilizer runoff, the restoration of indigenous plant communities, and the development of wildlife habitat to increase urban biodiversity. Furthermore, the term is often used to refer to water conserving landscapes within nonxeric environments. Given the importance of the residential lawn as an agent of environmental change and a cultural icon, the diffusion of xeriscaping is important as a harbinger of environmental attitudes,

environmental consciousness, and resource management practices of urban and suburban North Americans.

Landscape Management Practices

Xeriscaping encompasses a range of landscape management practices selectively adopted to conserve water. The precise selection of particular combinations of landscape elements and management practices is adapted to local and site conditions but typically integrates soil management, composting, mulching, and the planting of drought-tolerant plants with deep root systems. Xeriscaping practices vary by region depending on climate, native vegetation, soil types, land use, and other environmental factors. Landscape plans are typically developed to suit particular characteristics of a residential yard, such as soil types, exposure, slope, and grade, in order to maximize water retention. Xeriscaping often requires conversion of an existing turfgrass lawn to new ground covers that typically include native and drought-resistant grasses, shrubs, trees, and non-living surfaces. Mulches are often used to retain water and control weeds. Retention of areas of turfgrass is compatible with xeriscaping principals if located in appropriate water-use zones. Those who adopt xeriscaping often integrate personal aesthetic preferences into landscape design. Xeriscaping advocates often emphasize

Funded in part by a grant from the Arizona Department of Water Resources, the Tempe Women's Club Park was converted to a Xeriscape Demonstration Garden in 1995 to promote low-water-use plants and desert landscaping practices.

Source: Richard Bond, City of Tempe Water Conservation Program.

the individuality of landscape design that can be incorporated into landscape plans, in contrast to the relatively uniform conventional lawn.

Other Environmental Benefits

Although the term suggests management for reduced water consumption, xeriscaping is commonly associated with a range of environmental objectives that residents seek to realize through their landscape choices. Due to health concerns, especially for children and pets, eliminating or reducing applications of chemical pesticides has

been highlighted as a benefit of xeriscaping. Regional environmental impacts of landscaping choices are also highlighted by xeriscaping proponents. For example, in coastal Florida, environmental scientists believe that the incorporation of native vegetation into residential landscaping practices will reduce the impact of nonpoint source pollution on coastal ecosystems. However, additional environmental amenities, such as the restoration of wildlife habitat and increased urban biodiversity, can be problematic for residents who fear that wildlife may interfere with their enjoyment of their yards.

Geography of Xeriscaping in North America

The popularity of xeriscaping—as well as the particular forms xeriscaped landscapes have taken—is partly a reflection of efforts by state, county, and city governments to promote resource conservation in residential landscaping. Initially, such efforts were primarily concentrated in the mountain west, southwest, and southeast portions of the United States. In these states, recent migrants from the Midwest and the Northeast have often reproduced landscape patterns similar to those in their home regions without recognition of the limitations of available water resources. Currently, most U.S. states sponsor public education or extension programs that promote xeriscaping as a means of reducing water consumption and addressing other local and regional environmental problems.

Social Dimensions of Xeriscaping

Land area under turfgrass lawn in urban and suburban North America has expanded greatly over the past three decades and unquestionably dominates the American residential landscape. The more recent and more modest trend toward adoption of xeriscaping thus represents an important alternative to the turfgrass lawn. Xeriscaping might thus be seen as a reaction to the uneasy relationship that North Americans have with their lawns, including their concerns about domestic water consumption and health and safety concerns associated with chemical-intensive turfgrass landscaping. Moreover, the growth of xeriscaping raises important questions about the environmental aesthetics of North American residential landscapes and the values and perceptions of socio-environmental spaces as reflected in landscaping decisions.

Despite its growing popularity, the continued diffusion of xeriscaping practices faces legal, cultural, and financial obstacles. Although many states have gone so far as to develop county extension programs to assist homeowners in integrating xeriscaping principles into their landscaping practices, city ordinances and deed community regulations may restrict the conversion of conventional landscapes into xeriscaped landscapes.

Cultural values are often at stake in such landscape conversions, and resistance by neighbors is

common. Cultural obstacles are often created by pressure from neighbors who fear a break with the uniformity of neighborhood lawns. Additional concerns cited by neighbors of those who adopt xeriscaping include fear of declining property values as a result of unkempt yards and fears of unwanted wildlife.

The transformation of turfgrass lawns into xeriscaped yards often requires that homeowners make significant time and financial investment in their yards. Even established xeriscaped landscapes may require substantial maintenance. Many residents rely on private landscaping firms that specialize in environmentally friendly landscaping for advice and guidance. Such expenses represent a financial barrier to the adoption of xeriscaping by low-income households. Thus, the diffusion of xeriscaping and the above obstacles to wider adoption reflect the cultural, political, and economic complexities that accompany shifts toward urban environmental sustainability.

ZELINSKY, WILBUR (1921–)

Wilbur Zelinsky is an iconic cultural and population geographer who focuses on finding big-picture geographical manifestations of human meaning in every detail and facet of American life. He is an expert in field-based exploration, archival research, quantitative and qualitative analyses, cartographic representation, and clear and direct writing. His work reflects an unusual originality and continues to inform scholars in many disciplines.

Zelinsky was born in Chicago and began his academic career at Wright Junior College. He completed his baccalaureate at the University of California at Berkeley in 1944, earned a master's degree from the University of Wisconsin in 1946, and returned to Berkeley for his PhD, which he completed in 1953. His early work experiences trained him for observation and analysis. He was a map draftsman in various firms during World War II, a terrain analyst for the Army Corps of Engineers in Occupied Germany in 1946, and an industrial location analyst for the Chesapeake & Ohio Railway from 1954 to 1959. His academic appointments include the University of Georgia from 1948 to 1952, the University of Wisconsin as a researcher from 1952 to 1954, Wayne State University as an adjunct professor from 1954 to 1959, and Southern Illinois University from 1959 to 1963. He joined the geography department at

Pennsylvania State University in 1963, where he has remained ever since. He was department head from 1970 to 1976, assumed emeritus status in 1987, and continues as an active scholar.

Zelinsky's publication record includes more than 200 books, atlases, chapters, articles, reviews, and reports, not counting reprints and second editions. Topics he has studied include cemeteries and cemetery names, energy consumption, food ways, log houses, migration, nationalism, personal names, place names, rural population distribution, settlement patterns, town forms, and vernacular regions. His first published article in 1948 was perhaps the first by any geographer on African Americans. His hypothesis of the mobility transition (an increase in rural to urban migration followed by an increase in intra- and interurban migration with modernization) is a significant complement to the concept of demographic transition (a decrease in death rates and, subsequently, birth rates occurring with modernization) both operationally and intellectually. He was the first geographer to write about the place of women in the profession. His 1974 presidential address to the Association of American Geographers (AAG), "The Demigod's Dilemma," was an important early humanistic call to rethink overly scientific premises in the social sciences. His scholarly focus in recent years has been the landscape effects of religion and the meaning of ethnicity.

Zelinsky was president of the AAG from 1972 to 1973, and honors include the AAG's 1966

Award for Meritorious Contributions to Geography, a Guggenheim Fellowship from 1981 to 1982, and the 1993 Jackson Prize for the revised edition of his best-known work, a slim book titled *The Cultural Geography of the United States*. He received the American Geographical Society's Cullum Medal in 2001 and the AAG Presidential Achievement Award in 2006.

be used for. Zoning has been studied by political geographers interested in the exercise of governance and by economic geographers interested in the consequences of these laws on land values and economic activity. Zoning has also been extended to classifying and preserving the physical attributes of land on flood plains, steep slopes, and wetlands, and other characteristics. The idea of zoning has also been expanded to consider more generally the spatial isolation of populations or activities by local governments and policing activities.

Discursively, zoning is often tied to the idea of social disorganization and the apparent need to reconstitute order in cities. Such arguments hinge on the assumption that an increasingly complex urban life necessitated the need for “order” and the separation of private dwellings from buildings for commercial and industrial use. Historians of zoning regulations have diverging arguments about the original function of these laws. Some argue that zoning was meant to prevent the encroachment by the lower classes and people of other ethnicities on high-land-value neighborhoods, such as garment workers in New York and Chinese laundries in California. Conversely, other scholars argue that zoning laws were meant to protect the lower classes from the deleterious health effects of industrial production and overcrowding. Whether the original crafters of the American zoning law had socially progressive intentions in mind or not, the discourse of “order” and the desirability of “separation” have been enormously important in shaping public understanding of zoning. “Order” has turned out to mean many things in zoning, from regulating new development to redirecting nearly all capital production to licensed, commercially zoned districts. This discourse continues to inform and justify daily practices of zoning and can be evidenced in much of the research on zoning.

Political geographers have couched zoning in the larger context of governance and used it to reveal power relations and social inequities. Such geographers consider the wider political processes that allow counties and municipalities to use zoning laws to manage behavior through enforcement practices, to enforce state power over privately held property, and to generate spatial data on property. These articulations produce a

ZONING

Initially introduced in New York in 1916 and quickly spreading to nearly all large American urban areas, zoning is a practice of municipal or county government land segregation according to use, density, building height, and lot size. Zoning is a police power permitting governments the right to refuse permission to use land in ways differing from the zoning code. Zoning is often equated with city and county planning processes but functions differently in reality. Zoning is considered a “negative” tool in that cities only have a right to deny a land use application rather than designating exactly what the property can

Figure 1 Map of zoning districts within the city of San Leandro, California

legalized and enforceable landscape, dictating what activities citizens can perform and where. Political geographers regard regulatory agencies generally, and zoning particularly, as a way to produce a regulated urban landscape, cultivate legitimacy, and produce governable populations. Some zoning literature focuses on the regulatory enforcement, that is, the multiple ways the state shapes society through local enforcement, ideologies, and policies.

Economic geographers have focused on the effects of zoning laws on land values and optimal zoning designations for wealth accumulation. Such analysis of zoning has frequently taken the form of large-scale quantitative studies, often with Houston, the only major American city without zoning laws, serving as a foil.

The legal geographies literature has provided important groundwork to consider the ways law generally is spatially produced at different scales. Scholars of property have looked to zoning regulations to better understand the relationship between property, citizens, and the state. Geographies of social control have taken the zoning concept of separation and isolation and used it in different ways to explore social exclusions. Social control literature has focused on the “zoning” of people, applying the logic of land use law and exclusion to individuals or classes of people. Researchers of social control have emphasized the way particular groups or behavior have been legally defined, isolated, and located by the law. Geography and social control literature has focused on the exceptions built into the law by focusing on marginal populations such as the homeless, sex workers and adult businesses, political activists, and drug culture participants.

Criticisms of Zoning

Zoning has been tied to exclusionary practices intended to limit affordable housing and housing plurality. This constraint often takes the form of inflated property size restrictions and low-density requirements, presenting obstacles to mixed-income housing and, effectively, achieving some degree of racial segregation. Such results arguably reinforce class divisions and limit opportunities to attain housing equity. More recently, inclusionary zoning practices have attempted to

provide more affordable housing options and grant incentives for developers to produce a range of affordable to moderately priced properties. Inclusionary zoning establishes municipal and county ordinances that mandate a certain percentage of affordable housing be developed among otherwise market-rate housing. Such practices are an attempt to bypass the economically exclusive practices of zoning laws. Inclusionary zoning has been criticized by developers for adding onerous regulations and by affordable housing advocates for placing unrealistic expectations given the powers afforded to zoning. Furthermore, criticism has been lodged about the ways such laws are administered. Zoning laws are non-retroactive, producing an uneven landscape of conforming and nonconforming properties.

Globally, cities and countries frequently have land use regulations and reviews of new development projects, though the police-power based zoning seen in American cities is infrequently implemented. The American model of zoning was initially imported from Germany. Zoning regulations were adopted in Canadian cities subsequent to their adoption in the United States.

ATLAS OF THE WORLD: A BRIEF CARTOGRAPHIC OVERVIEW

The *Encyclopedia of Geography* includes the following 18-page atlas as a convenient source for political maps of the world. This section also includes a global topographical map of the world and examples of some of the principal map projections used in depicting the world. In addition, the A–Z entries include numerous world maps relevant to both physical geography (e.g., angiosperm family richness, global distribution of deserts, ecoregions, the Köppen-Geiger climate classification) and human geography (e.g., colonial migrations, human development, famine-prone regions, Internet penetration rate). See the entries under “World maps” in the index at the end of this volume for a complete listing.

The maps included here offer a basic overview; however, space limitations do not allow for detailed depictions of countries and major cities. The *College Atlas of the World* published by Wiley and National Geographic is a useful source not only for more extensive political maps and other information in human geography but also for a global view of many aspects of physical geography.

For more detailed maps in human and physical geography:

Map Projections

Cartographers use a variety of projections to represent the spherical surface of Earth on a flat map. Because it is mathematically impossible to render a globe on a plane without changing the spatial configuration of the data involved, all such mapping involves some degree of distortion, so in choosing a projection, the cartographer will consider what properties are most important to preserve, at the cost of some other properties. For example, projections may accurately represent or distort the area (equivalence), shape (conformality), direction, distance, and scale of Earth's features, but not all of these simultaneously. Projections are important because maps shape how we view the world, and their distortions often enter into our geographical imaginations. Different types of projections are useful for different cartographic purposes. See the Map Projections entry in this encyclopedia for a detailed description of different types of projections.

The majority of the maps in this encyclopedia use the Mercator projection, developed in the 16th century by Gerardus Mercator, a Flemish cartographer. Intended for navigation, it uses a rectangular grid that shows constant bearings as straight lines, and hence became popular among navigators. It remains the most commonly

used map projection today, reproduced in countless classrooms, atlases, and textbooks. However, the Mercator projection greatly exaggerates the size of areas at higher latitudes (for example, Greenland is only as eighth as large as South America, but its area appears much greater on a Mercator map). In 1989, several North American geographical organizations passed a resolution urging the use of alternative projections.

The Mollweide projection, created in 1805 by the German mathematician Carl B. Mollweide, is a more accurate representation of the size of areas, but distances and shapes are distorted.

The Fuller dymaxion projection, created by R. Buckminster Fuller in the mid 20th century, is useful in showing the interconnectedness of Earth's landmasses and has less distortion of areas than the Mercator projection. It is used in this encyclopedia to show Earth's cryosphere (see Ice entry).

Developed in 1923 by John Paul Goode, the interrupted Goode homosoline projection presents the world in discrete regions in order to minimize distortions of size and shape. It is useful for showing raster data, in which a geographical area is divided into cells identified by row and column.

Mercator projection: This projection distorts the size of regions far from the equator. For example, Greenland appears to be larger than South America, but in fact, South America is eight times larger.

micropits and etched surfaces, 4:1653
mogotes (haystack hills), 4:1652
natural bridges, 4:1652
phreatic caves, 4:1651
phytokarst, 4:1654
pinnacle karsts and stone forests, 4:1653
pipino hills, 4:1652
pond dolines, 4:1651
psuedokarst, 4:1650
rock solubility and, 4:1649
rounded solution runnels or rundkarren, 4:1653
ruinform karsts, 4:1653–1654
shallow phreatic, epiphreatic, or water table caves, 4:1651
sinkholes, or doline types of, 4:1651
size scale classification of, 4:1651
smaller forms of, 4:1652–1653
solution bevels, 4:1653
solution dolines, 4:1651
solution flutes or rillenkarren, 4:1653
solution notches, 4:1653, 4:1654
solution pans, 4:1653
solution pipes, shafts, or wells, 4:1653
solution pits, 4:1653
solution ripples and fluted scallops, 4:1653
solution runnels or rinnenkarren, 4:1653
solution slots or grikes and kluftkarren, 4:1653
solution spikes or spitzkarren, 4:1653
splitkarren or solution fissures, 4:1653
steepheads and pocket valleys, 4:1652
stream-sink dolines, or ponors, 4:1651
structural polja, 4:1652
subsidence dolines, 4:1651
suffusion dolines, 4:1651
thermokarst, 4:1650
true karst, 4:1650
tufa and travertine deposits, 4:1652
undercut solution runnels (Hohlkarren), 4:1653
uvalas and polje, 4:1651–1652
vodose caves, 4:1651
- Kates, Robert, 4:1654–1655**
ending hunger focus of, 4:1654
human use of the earth focus of, 4:1654
nature-society relationships and, 4:1654
risk assessment perspectives of, 4:1654
service work of, 4:1654
sustainability focus of, 4:1654

 user-centered design approach and, 4:1832

Map generalization, 4:1833–1841

agent-based modeling and, 4:1834
 application of cartographic license concept and, 4:1836, 4:1836 (fig.)
 cartographic generalization, 4:1834, 4:1836, 4:1836 (fig.), 4:1837, 4:1838 (fig.)
 “cartographic syntax” framework research and, 4:1840
 data enrichment concept and, 4:1837
 decision-making in, 4:1837
 definition of, 4:1833–1834
 digital paradigm shift and, 4:1834
 evaluation of, 4:1837, 4:1839
 “eyes of the cartographer” requirement and, 4:1834, 4:1839, 4:1840 (fig.)
 isopleth maps and, 3:1638–1639
 model and cartographic generalization and, 4:1834–1836, 4:1836 (fig.)
 model generalization, 4:1834, 4:1836–1837, 4:1836 (fig.), 4:1838 (fig.)
 mutiscale processes interaction and, 4:1833–1834
 Portsmouth, England, at three scales and, 4:1834, 4:1835 (fig.)
 primary digital landscape model (DLM) and, 4:1834, 4:1836 (fig.)
 retail park in Southampton, England, 4:1838 (fig.)
 secondary DLMs and, 4:1834, 4:1836 (fig.)
 techniques to improve map legibility and, 4:1834 (fig.), 4:1839 (fig.)
 Voronoi modeling example and, 4:1837, 4:1839, 4:1840 (fig.)

Map projections, 4:1841–1849

Albers equal-area projection, of North America, 4:1846 (fig.), 4:1847
 Buckminster Fuller or “Dymaxion map” projection, 6:3169
 compromise projections and, 4:1842
 conformity (shape) property of, 4:1842
 coordinate geometry and, 2:577–579
 coordinate system and datum elements of, 4:1841
 coordinate transformations and, 2:580–581
 direction property of, 4:1842
 distance property of, 4:1842
 equal area or equivalence property of, 4:1842
 geodesy and, 3:1217–1219
 geometric measures and, 3:1240–1241
 Good’s Interrupted Homolosine projection and, 3:1351, 3:1351 (fig.)
 interrupted Goode homolosine projection, 3:1351, 3:1351 (fig.), 6:3169
 Lambert conformal conic projection, of North America, 4:1846 (fig.), 4:1847–1848
 Mercator projection, 4:1843 (fig.)
 Mollweide projection, 4:1844, 4:1844 (fig.), 6:3152–3153, 6:3169
 Plate Carrée projection, 4:1844, 4:1846 (fig.)
 portolan charts and, 5:2251–2252
 projection definition and, 4:1841

See also Geomorphic cycle; Geomorphology; Physical geography,
history of: *specific timeline below*
- Physical geography, history of: early Greek and Roman
Aristotle, 4:2178
Earth as a spherical shape and, 4:2178
Earth's circumference calculation and, 4:2178
Eratosthenes, 4:2178
Geographica (Strabo) and, 4:2178
Guide to Geography (Ptolemy) and, 4:2178
latitude and longitude concepts (Ptolemy) and, 4:2178, 5:2300
Ptolemy, 4:2178, 5:2300, 5:2387
Roman empire expansion and, 4:2178
Strabo, 4:2178
- Physical geography, history of: Middle Ages to 1800
al-Idrisi, 4:2179
Arab geographers, 4:2179
Martin Behaim, 4:2179
Geographia generalis (Varenus) and, 4:2179, 5:2387
geography branches of knowledge (Kant) and, 4:2179
geography subdivisions (Varenus) and, 4:2179, 5:2387
human knowledge subdivisions (Kant) and, 4:2179
Ibn Battutah, 4:2179
Ibn Khaldūn, 4:2179
Immanuel Kant, 4:2179
knowledge organization (Kant) and, 4:2179
Renaissance exploration and, 4:2178, 4:2179
spherical globe (Behaim) and, 4:2179
technology advances and, 4:2179
Viking exploration and, 4:2178
- Physical geography, history of: 1800–1950
Louis Agassiz, 4:2180
American Geographical Society and, 4:2180
Frederic Clements, 4:2180
climate classification (Köppen) and, 4:2180
Henry Cowles, 4:2180
cycles of erosion and landscape development
(W. M. Davis) and, 4:2180
Charles Darwin, 4:2180

- data collection and classification and, 4:2181
 William Morris Davis, 4:2180
 V. V. Dokuchaev, 4:2180
 geographical societies and, 4:2180
 geography subviews and, 4:2180
 G. K. Gilbert, 4:2180–2182
 glaciation research (Agassiz) and, 4:2180
 human degradation of environment (Marsh) and, 4:2180
 Alexander von Humboldt, 4:2180
 James Hutton, 3:1245, 4:2179–2180
 Wladimir Köppen, 4:2180
Kosmos (Humboldt) and, 4:2180
 landscape evolution research (Gilbert) and, 4:2180–2181
 Charles Lyell, 4:2179–2180
 George Perkins Marsh, 4:2180
 pedology (Dokuchaev) and, 4:2180
 plant succession theories (Clements and Cowles) and, 4:2180
Principles of Geology (Lyell) and, 4:2180
 Carl Ritter, 4:2180, 5:2387, 5:2470–2471
 theory of evolution and, 4:2180
 theory of uniformitarianism and, 4:2179–2180
 Alfred Wallace, 4:2180
- Physical geography, history of: 20th century, second half**
 academic departments and, 4:2181
 biodiversity issues and, 4:2181
 global warming issues and, 4:2181
 Arnold Guyot, 3:1394
 Ferdinand Hayden, 3:1408–1409
 human activities issues and, 4:2181
 Walther Penck, 4:2145
 physical geography as a discipline and, 4:2181
 quantitative revolution and, 4:2181
 remote sensing and GIS tools and, 4:2181
 systems-theory approach to, 4:2181
 C. Warren Thornthwaite, 6:2821–2822
- Physical geography, history of: 21st century**
 environmental issues and, 4:2182
 human population growth issues and, 4:2182
 information-processing technology and, 4:2182
 interdisciplinary collaborations and, 4:2182
 measurement technology advances and, 4:2182
 remote sensing and satellite technology and, 4:2182
 resource consumption issues and, 4:2182
- Piaget, Jean, 1:391, 5:2609, 5:2610
 Pick, J., 1:308
- Pickles, John, 4:2182–2183**
 alternative mappings of contemporary society and, 4:2183
 changing global economic geographies and, 4:2183
 Counter-Cartographies Collective and, 4:2183
 critical cartography work of, 4:2183
 critical GIS and critical geography work of, 4:2182–2183
 critical social theory and, 4:2182, 4:2183
 existentialism and, 2:1046
 globalization of apparel industry studied by, 4:2183
Ground Truth written by, 4:2182
A History of Spaces written by, 4:2183
 phenomenology and spatiality work of, 4:2183
 political economies of power and development work of, 4:2183
 regional analysis work of, 4:2109
- Pigou, Arthur, 4:1857
- Pilgrimage, 5:2184–2186**
 criticism of, 5:2184
 cultural and political developments related to, 5:2184
 definition of, 5:2408
 group rituals and, 5:2184
- Holy Mecca in Saudi Arabia, 5:2185 (photo)
 importance of, 5:2184
 modern tourism and, 5:2185
 national shrines and, 5:2184
 as religious focal points, 5:2184
 revived interest in, 5:2184
 as sacred demand response, 5:2184
 sacred places, religious geographies and, 5:2407–2408
 site examples of, 5:2184
See also Religion, geography and
- Pinchot, Gifford, 2:570
 Pinder, John, 2:1037
 Piraro, Dan, 3:1219 (image)
 Pittsburgh, Pennsylvania, 4:1821
- Place, 5:2186–2188**
 building and dwelling connections and, 5:2187
 decentering of authoritative knowledge and, 5:2187
 geographical self, 5:2187
 home as a metaphor for, 5:2186–2187
 human agency and, 5:2187
 human geography and, 5:2186
 human identity and, 5:2187
 humanist geography and, 5:2186–2187
 integrative approaches regarding, 5:2187
 locality studies and, 4:1790–1792
 palimpsest concept and, 4:2111–2112
 place is associational and, 5:2187
 production of space and, 5:2297–2298
 Edward Relph, 5:2410–2411
 social production of spaces and, 5:2187
 space/place issue and, 5:2186
 spatial science and, 5:2186
- Place names, 5:2188–2191**
 conflicts of use and spellings of, 5:2189
 Dr. Martin Luther King Jr. Boulevard in Harlem, New York City, and, 5:2190 (photo)
 function of, 5:2188
 gazetteers and, 3:1185–1186
 geocoding and, 3:1208–1209
 image-generating power of, 5:2189
 naming as resistance by marginalized groups and, 5:2190
 permanence of, 5:2189
 powerful connotations and, 5:2189
 power relations and, 5:2189
 sense of order and familiarity and, 5:2189
 as spatial reference, 5:2189
 study of, 5:2190
 as symbols, 5:2189
 taking ownership of places and, 5:2189
 toponymy and, 6:2840–2850
 United Nations Group of Experts on Geographical Names (UNGEGN) and, 5:2189
- Place promotion, 5:2191–2192**
 academic foci, 5:2191–2192
 city image reformation and, 5:2191
 critical perspectives on, 5:2191–2192
 definition of, 5:2191
 historical context of, 5:2191
 investment capital attraction and, 5:2191
 marketing efforts and, 5:2191
 mass transit evolution and, 5:2191
 railroads, frontier development and, 5:2191
 suburbs and, 5:2191
 tourism and, 5:2191
- Plantations, 5:2192–2195**
 agro-economic production and, 5:2192

- biofuels crops and, 5:2194
- blue agave plantation, Tequila, Mexico, 5:2194 (photo)
- boom crops of, 5:2193
- characteristic variations of, 5:2192–2193
- colonial and postcolonial history of, 5:2192
- community-based natural resource management and, 5:2194
- definition of, 5:2192
- deforestation and, 5:2193
- ecological effects of, 5:2195
- forest conservation mechanisms and, 5:2194–2195
- forest industries and, 5:2195
- global development institutions and, 5:2193
- global forestry institutions and, 5:2194–2195
- Great Depression and, 5:2193
- hacienda form of, 5:2193
- land and resource conflicts, 5:2194
- as organizational form, 5:2192
- payments for ecosystem services and, 5:2195
- rural insurgencies suppression and, 5:2192
- smallholder plantations and, 5:2195
- social countermovements and, 5:2194
- state control, political-economic power and, 5:2192
- state subsidies and, 5:2194–2195
- tea plantation Cameron Highland, Pahang, Malaysia, and, 5:2193 (photo)
- total institutions, characteristics of, 5:2192
- Plate tectonics, 5:2195–2199**
 - African rift system and, 5:2197
 - aseismic creep and, 2:605
 - convergent (destructive/active) plate boundaries and, 5:2196, 5:2197 (fig.), 5:2198
 - coral reef morphology and, 2:586
 - divergent (constructive) plate boundaries and, 5:2196, 5:2197–2198, 5:2197 (fig.)
 - driving forces in, 5:2198–2199
 - Earth's composition and, 5:2195–2197
 - explosive volcanism and, 5:2198
 - faulting and, 3:1085–1088
 - geologic timescale and, 3:1235–1238
 - geomorphology of Earth's crust and, 5:2195
 - gravity factor in, 5:2198
 - hot spots and, 5:2197
 - Iceland and, 5:2197
 - major lithospheric plates, plate boundaries, directions and rates of, 5:2196, 5:2196 (fig.)
 - Pacific Ring of Fire and, 3:1273
 - paleoclimatology and, 1:471
 - seafloor spreading and continental drift concepts and, 5:2195
 - sea level changes and, 1:494
 - slab pull factor in, 5:2198–2199
 - subduction rollback and, 5:2199
 - teothermal features and, 3:1273
 - transform (conservative) plate boundaries and, 5:2198
 - See also* Diastrophism; Earthquakes; Geomorphic cycle; Geomorphology; Landforms
- Platforms and sensors**
 - LiDAR and airborne laser scanning and, 4:1778–1779
 - See also* Remote sensing
- Plato**
 - absolute space views of, 1:2
 - antipodes, 1:98
 - conservation views of, 5:2584
 - environmental determinism views of, 1:2
 - ethics views of, 2:1013
 - ideal size of political unit views of, 5:2217
 - political impact of geography and, 5:2215
 - social justice issues and, 5:2572
- Playas, 5:2199–2201**
 - definition of, 5:2199
 - ecosystem functions of, 5:2199–2200
 - Great Basin lakes and, 5:2199
 - North American High Plains of Great Plains and, 5:2199
 - origins of, 5:2199
 - playa and associated lunette and, 5:2200 (photo)
 - playa lake term and, 5:2199
 - small playa in winter wheat field, High Plains, 5:2200 (photo)
 - terms related to, 5:2199
- Plumwood, Val, 2:831, 3:1100
- Pohnpei, 3:1634
- Point pattern analysis, 5:2201–2202**
 - complete spatial randomness (CSR) and, 5:2201
 - definition of, 5:2201
 - first-order properties of a spatial point pattern and, 5:2201–2202
 - geographic quantitative revolution and, 5:2201
 - interevent distances distribution and, 5:2201–2202
 - local clustering examination using, 5:2202
 - plant ecology and, 5:2201
 - quadrat methods and, 5:2201–2202
 - as spatial statistics branch, 5:2201
 - theoretical models used in, 5:2201
 - trends for events to exhibit a pattern and, 5:2201
- Point sources of pollution, 5:2203**
 - air pollution, 5:2203
 - area sources and, 5:2203
 - atmospheric dispersion modeling and, 5:2203
 - atmospheric pollution and, 1:151–155
 - definition of, 5:2203
 - emissions trading systems to control, 5:2203
 - government regulation of, 5:2203
 - Love Canal and, 4:1806–1808
 - mobile sources and, 5:2203
 - nonpoint sources of pollution and, 4:2039–2040
 - oil spills and, 4:2073–2076
 - photochemical smog and, 4:2171–2173
 - stationary sources and, 5:2203
- Poland**
 - acid rain in, 1:7
 - AGILE membership of, 1:125 (table)
 - automobile industry in, 1:171
 - cancer rates studies of, 1:336
 - Clean Development Mechanism (CDM), carbon offsets and, 1:333 (fig.)
 - coal energy source in, 3:1582
 - COMECON membership of, 2:593 (table)
 - ecological footprint and biocapacity of, 2:827 (table)
 - economically active females in, 3:1190 (table)

Spatial fix, 5:2638–2640

capital accumulation and, 5:2639
 grounded capital and the built environment in, 5:2639–2640
 David Harvey and, 5:2638, 5:2639
 Marxist geographies and, 5:2638
 relative/relational space and, 5:2402–2405
 spreading out of capital and, 5:2638–2639
See also **Spatial specific subject**

Spatial inequality, 5:2640–2645

dynamic of change across different spatial scales and, 5:2642
 educational geographies and, 2:874–875
 girls' education, Gansu, China, 5:2642 (fig.)
 income ratio relative to slum population, global
 South countries, 5:2644 (fig.)
 local, national, regional, or global scale of, 5:2641–2642
 per capita income in West Bengal districts, India, 5:2643 (fig.)
 quantification of, 5:2640
 quantitative analysis and, 5:2643
 socioeconomic clustering feature of, 5:2640, 5:2641 (fig.)
 unequal distribution in goods or services and,
 5:2640–2641, 5:2642 (fig.)
 world income distribution across four countries, 5:2641 (fig.)
See also **Spatial specific subject**

Spatial interaction models, 5:2645–2647

applications of, 3:1169
 competing destination model (Fotheringham) and, 3:1169
 destination-specific attributes in, 5:2645
 discrete zone systems element of, 5:2645
 distance decay theory and, 2:774–776
 A. Stewart Fotheringham's work in, 3:1169
 functions of, 5:2645
 mathematical expression of, 5:2646
 network analysis and, 4:2016–2018
 network data model and, 4:2018–2019
 neural spatial interaction models and, 5:2647
 origin-destination variables in, 5:2645
 origin-specific attributes in, 5:2645
 spatial information processing linked to, 3:1169
 spatial interaction definition and, 3:1169
See also **GIS specific subject**; **Spatial specific subject**

Spatial interpolation, 5:2647–2649

Bayesian kriging and, 5:2648
 computation of, 5:2648

deterministic interpolation and, 5:2648
 functions of, 5:2647
 geometric correction and, 3:1239–1240
 geostatistics and, 3:1261–1265
k-nearest neighbor search example of, 5:2648
 point *vs.* are entities and, 5:2648
 taxonomy and, 5:2647–2648
 Tobler's first law of geography and, 5:2648

See also **GIS specific subject**

Spatialization, 5:2649–2653

alternate meanings of, 5:2652–2653
 challenges in, 5:26512652
 data sets to be spatialized and, 5:2650
 definition and purpose of, 5:2649
 dimensionality reduction techniques and, 5:2650–2651
 dimensional reduction concept and, 5:2650
 examples of, 5:2651
 geographic knowledge domain example of, 5:2652 (fig.)
 graph layout methods of, 5:2651
 methods of dimensionality reduction and spatial layout in,
 5:2650–2651
 network of influential authors example of, 5:2652 (fig.)
 network structure data sets and, 5:2650
 production of space and, 5:2297–2298
 sound spatialization term and, 5:2653
 spatial layout approaches of, 5:2651
 spatial metaphors and, 5:2649
 tree map method and, 5:2651
 types of applications and data in, 5:2649–2650
See also **Spatial specific subject**

Spatially integrated social science, 5:2654–2655

analytical approaches to, 5:2654–2655
 definition of, 5:2654
 development of, 5:2654
 geographically weighted regression and, 5:2655
 geographic contexts of, 5:2654
 integrative computer-based tools and, 5:2654
 Markov random field segmentation and, 5:2655
 place-or locality-based analysis approach to, 5:2655
 social spaces and, 5:2654
 space and place elements in, 5:2654
 spatial analysis approach to, 5:2655
 time-geography and space-time behavior examples of, 5:2654
See also **Spatial specific subject**

Spatial multicriteria evaluation (spatial MCE), 5:2655–2657

alternatives identification and, 5:2656
 analytical hierarchy process (AHP) and, 5:2656
 applying a decision rule in, 5:2656–2657
 Marc Armstrong's work in, 1:117
 criteria and standardizing data values in, 5:2656
 criticisms, 5:2657
 generating criteria weights in, 5:2656
 ideal-point analysis (IPA) and, 5:2656
 identifying alternatives, 5:2656
 integrative origins of, 5:2655
 methodology of, 5:2655–2657
 outranking techniques and, 5:2656–2657
 semistructured problems and, 5:2655
 sensitivity analysis in, 5:2657
 terms related to, 5:2655
See also **GIS specific subject**; **Spatial specific subject**

Spatial optimization methods, 5:2657–2659

artificial intelligence heuristics and, 3:1215
 formulating an objective function element in, 5:2657–2658
 functions of, 5:2657

- genetic algorithm, 5:2659
 genetic algorithms, 3:1215
 geocomputation and, 3:1215
 GIS analytical operations and, 1:71–72
 greedy algorithm, 5:2658
 heuristics used in, 5:2658–2659
 limitations of, 3:1215
 location-allocation modeling, 4:1793–1794, 5:2657
 metaheuristics algorithm, 5:2659
 naive or random strategy algorithm, 5:2658
 simulated annealing, 3:1215
 simulated annealing algorithm, 5:2658
 single and multiple objectives approach to, 5:2658
 tabu search list, 5:2658–2659
 total enumeration algorithm, 5:2658
See also GIS specific subject; Heuristic methods in spatial analysis; Spatial specific subject
- Spatial resolution, 5:2659–2663**
 aerial photography and, 5:2662–2663
 analog maps and, 5:2660–2661
 definition of, 5:2659
 error propagation and, 2:1011–1012
 field data and, 5:2663
 general considerations in, 5:2659–2660
 geographically relevant parameters in, 5:2660, 5:2660 (fig.)
 image interpretation and, 3:1534–1536
 modifiable areal unit problem and, 4:1935
 optimal spatial resolution determination, 5:2663
 raster data and, 5:2662–2663 (fig.)
 satellite images and, 5:2662–2663 (fig.)
 vector data and, 5:2661–2662, 5:2661 (fig.)
